Asset-Backed Securities:

Costs and Benefits of “Bankruptcy Remoteness”*

First Draft: August 2004
This Draft: March 2005

Abstract

Asset-backed securities (ABS) are increasingly becoming an important part of the capital structure decisions of both financial and non-financial firms. In this paper, we focus on a key property of these contracts; namely, that ABS are designed to achieve “bankruptcy remoteness” of the securitized assets from the borrowing firm. This provides lenders with maximal protection from dilution in bankruptcy that is not available with other contractual forms, such as secured debt. ABS can have real effects in allowing firms to commit to more efficient investment decisions in bankruptcy. We show that securitization of replaceable assets, such as accounts receivable, is particularly valuable in preventing inefficient continuation in bankruptcy, but securitization of necessary assets can lead to inefficient liquidations. In these circumstances, secured debt and/or leases can be preferred because they provide stronger limitations on creditor rights.

We provide empirical support for the model by examining the effects on credit spreads in the ABS market following the Chapter 11 bankruptcy of LTV Steel, which cast doubt on the ability to achieve bankruptcy remoteness of securitized assets. Using a difference-in-differences approach, we find that ABS spreads for non-depository securitizers, who are eligible for Chapter 11, increased significantly more than spreads for insured depository (bank) securitizers, who are not Chapter 11-eligible, in the period following the LTV filing. The results demonstrate that the creditor protection provided by “bankruptcy remoteness” is indeed valuable and priced in financial markets.

*We would like to thank Patrick Bolton, Chris Mayer, Ed Morrison, Francisco Perez-Gonzalez, Suresh Sundaresan, and seminar participants at the Financial Innovation conference and Columbia Finance lunch for helpful comments.

1 Introduction

Theories of debt finance, ranging from the costly state verification literature (Townsend (1979), Gale and Hellwig (1985)) to the literature of incomplete financial contracts (Bolton and Scharfstein (1990, 1996), Hart and Moore (1994)) focus on the disciplinary role of debt in financial contracting. The distinguishing feature of debt in these models is the collection rights given to the lender following a default by the borrowing firm. In essence, these models assume that, once the borrower defaults, the lender can take possession of whatever assets remain in the firm and dispose of them as the lender pleases. Bankruptcy law is often referenced as the mechanism by which this transfer of control rights takes place.

While these theories capture the main feature that distinguishes debt from equity, they are less able to distinguish between several “debt-like” financial contracts, all of which give packages of priority and control rights to lenders, but vary in the strength of these rights in bankruptcy. In particular, bankruptcy law provides for very different treatment of unsecured and secured debt, leasing contracts, and the focus of this paper, a newer form of financing known as asset-backed securities (ABS). To the extent that capital structure affects investment decisions, the choice among these instruments can have important effects on firm value.

ABS is now used by many large corporations in the U.S. as a principal financing method. While the use of securitization has been traditionally associated with financial institutions, in fact, many non-financial firms are also employing the technique. In Tables 1 and 2, we document the fraction of securitization undertaken by financial and non-financial firms, by number of firms and by dollar volume. In Table 3, we report securitization volume by industry, as reported in Gaon (2004). The data indicate clearly that securitization is not purely a financial firm phenomenon, and is not confined to any particular industry. We will argue, instead, that the benefits and costs of securitization depend more on the type of asset being securitized, rather than the type of the borrowing firm. In order to do so, we must first gain an understanding of what makes ABS unique as a financing tool.

In terms of its design, ABS most resemble secured debt. Like in a traditional secured
loan, the firm uses its existing assets (such as accounts receivable) to back a loan.⁠¹ As a consequence, investors in ABS need be concerned primarily with the quality of the assets backing the loan rather than the firm’s assets as a whole. Unlike secured debt, however, securitization involves the transfer of ownership of these assets to a separate legal entity (a special purpose vehicle, or SPV) which then sells claims on the assets to outside investors in exchange for liquid funds.²

Understanding the value of the SPV as an intermediate issuance vehicle between the firm and the investors is crucial to understanding what makes ABS unique. The transfer of ownership of the underlying assets to a separate legal entity allows the firm to establish the bankruptcy remoteness of the SPV and the transferred assets. Herein lies the effective difference between secured debt and ABS. When the borrowing firm files for bankruptcy, assets that serve as a collateral for the debtor’s secured loan are considered part of the bankruptcy estate. Contrary to the common assumption in the contracting literature that the creditor can seize the collateral on demand, these assets are subject to an automatic stay which restricts the lender’s collection rights. The collateral can then be used to support the firm’s reorganization, provided the secured lender is given “adequate protection”, a flexible standard determined by a bankruptcy judge. In contrast, assets that were transferred in a “true sale” to the SPV are not considered part of the debtor’s bankruptcy estate, but instead, continue to be used for the benefit of the SPV investors.

The additional control rights provided by this bankruptcy avoidance mechanism has significant impact on the transaction: rating agencies assess the credit quality of ABS based on the likelihood that courts will consider the transaction a true sale instead of a secured loan, and significant legal effort is made to ensure that the collateral will indeed be kept separate from a bankrupt borrower.³ In light of this special feature of ABS, it is apparent that in

---

¹A securitizing firm is often referred to as “originator.”

²One may also argue that a second key difference between ABS and secured debt is the secured creditor’s recourse to the firm’s other, non-collateralized assets. In practice, however, this difference is not as clear as it may seem because the SPV is often “overcollateralized” with the firm retaining an equity interest in the SPV. This will be discussed in section 3.

³See for example, Standard & Poor’s “Legal Criteria for Structured Finance Transactions,” April 2002. For an account of the response of rating agencies to a key court decision that shed cloud over the likelihood of ever achieving true sale see Weber and MacCallum (1993). In this paper, we will assume that contracting parties can costlessly create a “true sale” if they so choose, which will be upheld in court. We discuss this issue later in the paper.
order to analyze its use as a distinct financing tool, we need a framework that explicitly models the difference between ABS and other “debt-like” securities in bankruptcy. This will allow us to generate testable predictions about the types of firms that use these securities and the circumstances in which they will be issued.

We construct a theoretical model that begins with an owner-manager who raises capital in a competitive credit market. The owner-manager chooses a capital structure at date zero to minimize his overall financing cost, thus maximizing his payoff if the firm succeeds. The equilibrium cost of outside funds will depend on the expected outcome should the firm be forced into bankruptcy at date one. Whether the firm is able to reorganize or liquidate in bankruptcy will depend on its ability to obtain new financing, which depends on both the quality of its ongoing projects, and its initial capital structure decision. Because existing claims are costly to renegotiate, and managers have a bias toward continuation of the firm, two possible sources of inefficiency may arise: the firm may continue inefficiently if it can obtain the necessary financing despite having negative-NPV projects, or it may liquidate inefficiently if it cannot obtain financing despite having positive NPV projects.

We attempt to model, as closely and as parsimoniously as possible, current practices in Chapter 11 bankruptcy with respect to the control rights and priorities afforded to the various classes of claims when a firm is insolvent. In particular, we follow the law in allowing the bankrupt firm to raise debtor-in-possession (DIP) financing which is senior to existing unsecured creditors. As in prior work, (Gertner and Scharfstein (1991), Triantis (1993), White (1989)) we find that this can lead to overinvestment and inefficient continuations. Because of our setup, the model applies most directly to both financial and non-financial firms that are eligible for Chapter 11, which constitute a substantial proportion of the securitization volume in the U.S. The model also applies, though less directly, to both financial institutions that are subject to FDIC receivership, and most firms that are subject to bankruptcy outside

---

4To our knowledge, we are the first to explicitly model the differences between such securities based on their treatment in bankruptcy. Acharya et al. (2004) contrasts the U.S. and U.K. bankruptcy codes but focuses only on the debt/equity decision. Frank and Goyal (2004) discuss the prevailing capital structure theories, which mostly concentrate on the effects of taxes, agency problems and bankruptcy costs but not the explicit bankruptcy procedure. The contingent claims valuation literature has been more attentive to particular features of the bankruptcy process. See for example, Francois and Morellec (2004).

5Empirical research (Dahiya et al. (2003), Carapeto (2003)) also finds a positive relationship between DIP financing and the likelihood of reorganization.
the U.S., since in these cases creditors also have stronger collection rights in a securitization than with other forms of lending.

The special priority status of securitization explains why ABS offers value to the firm. When the firm chooses ex-ante to securitize rather than to use unsecured debt, it is effectively left with fewer assets on its balance sheet and would require a commensurately larger infusion of cash in order to avoid liquidation. Effectively, since the assets backing the claims of the ABS investors are not part of the bankruptcy estate of the firm, DIP financing cannot prime them. All else equal, this reduces the incentives of the DIP lender to provide new funds, which can mitigate the excess continuation problem inherent in the bankruptcy law.

Of course, this feature by itself does not create a unique role for ABS in the capital structure, since secured debt also enjoys some protection from dilution by the DIP lender6. Following practice, we model the difference between ABS and secured debt by the different control rights given to the lender when the firm goes bankrupt. With ABS, the SPV, run in the interests of its investors, owns the underlying assets and cannot be forced to surrender them to the firm. On the other hand, the court’s ability to limit the secured creditor’s control rights may leave the secured creditor with less protection than a comparable ABS investor would receive. This implies that lenders operating in a competitive market will require higher interest rates on secured loans than on an equivalent ABS issuance.

The main results of the model are as follows. First, we find that ABS is most valuable when the underlying assets are replaceable assets such as accounts receivable or other non-specific inputs; i.e. assets that the firm can easily obtain from outside sources at a competitive price. In such circumstances, ABS provides maximal protection to creditors and subjects the bankrupt firm to a more stringent market test in order to receive new funds. When more of the existing assets-in-place are sold, the DIP lender’s investment decision depends more on the quality of the firm’s ongoing projects and less on his ability to dilute the claims of existing creditors. With respect to necessary assets, such as fixed assets, inventory, or intangibles, we find that ABS can produce significant ex-post inefficiencies which raise the firm’s overall cost of capital. When the securitized assets are essential to the firm’s ongoing

6Section 364(d) of the Bankruptcy Code allows the DIP lender to obtain a priming lien over existing secured creditors if necessary. Since this provision is rarely used in practice, we will not assume this is always available to the firm.
operations, the ABS investors have significant hold-up power over the firm. The attempt to exploit this power can lead to inefficient liquidations if ex-post bargaining is subject to imperfections.

In the case of necessary assets, we show that secured debt and/or leases can be preferred to ABS, because investors’ holdup power is reduced. With secured debt, the creditor’s rights are determined during the bankruptcy process, and vary with the realized liquidation value of the collateral. With leases, the firm is given an option to keep the underlying assets by assuming the lease, if it maintains the payments specified in the initial contract. We show that secured debt, because of its flexibility, is likely to be preferred when the liquidation value of the collateral is more uncertain. On the other hand, secured creditors are subject to dilution in bankruptcy that can lead to excess continuations. Lessors’ rights, which are determined contractually, are more protected from dilution than secured creditors, but offer less flexibility than secured debt.

Our theoretical model relies on the special protection provided by “bankruptcy remoteness” to distinguish asset-backed securities from contracts like secured debt. This naturally leads to the question of whether this distinction is actually important enough economically to affect prices in financial markets.\(^7\) In the empirical section of the paper, we investigate whether the additional creditor protection provided by the “bankruptcy remoteness” of ABS transactions is indeed valued by investors, as our model suggests. Our strategy uses a natural experiment provided by a bankruptcy court decision in which an ABS transaction was effectively recharacterized as secured debt. In the Chapter 11 bankruptcy of LTV Steel, in late 2000, the bankruptcy judge issued an interim order allowing LTV to use securitized assets as cash collateral in support of its reorganization, effectively treating the transaction as a secured loan. The decision caused substantial uncertainty in the ABS market, because it cast doubt on the “true sale” status of securitized assets and the ability to guarantee bankruptcy remoteness in ABS deals.

Using a difference-in-differences approach, we compare ABS spreads over maturity-matched swap rates in the six month period before and after the LTV decision for a panel of depos-

\(^7\)Iacobucci and Winter (2005, p. 171), for example, express doubt that bankruptcy costs are large enough to justify securitization.
itory and non-depository institutions that securitized assets during this period. Insured depository institutions are not eligible for Chapter 11; the insolvency procedure for these institutions is governed by the FDIC. FDIC receivership rules, in effect before the LTV bankruptcy, explicitly prohibit recharacterization of securitized assets of the kind that occurred in the LTV case. Thus, we expect that the LTV decision should have had a positive effect on spreads only for non-depository securitizers if bankruptcy remoteness is indeed an important factor in the pricing of these contracts. Consistent with our theoretical model, we find a significant difference-in-differences, whereby the spreads on ABS issued by non-depository institutions increased by approximately 25 basis points more than the control group in the period following LTV. The effect is strongly statistically significant and is robust to alternative specifications and the inclusion of relevant control variables.

The rest of the paper is organized as follows. In the next section we present our theoretical model and examine the effects of bankruptcy law on investment incentives. We show that the possibility of priming existing creditors may result in inefficient over-investment. In section 3 we show how securitization works to mitigate this inefficiency. In section 4 we contrast ABS with the external financing instruments that most resemble it - secured debt and leases. In section 5 we provide empirical support for the effects of bankruptcy remoteness using ABS data around the LTV bankruptcy. In Section 6, we outline the implications of our results for the regulatory policy towards securitization. Section 7 concludes.

2 Model Setup

We consider a two-period model where a wealthless owner-manager owns an investment project which requires an initial fixed cash outlay of $I_0$ at period 0 from outside investors. The outside investor(s), which operate in perfectly competitive markets, are given claims on the project which require a total repayment of $F$ at period one. The outside claims can be of several types, which we summarize below. The project produces a random cash flow at period 1 of either $X_1^h > 0$ (with probability $p_1$) or 0 (with probability $1 - p_1$).

To focus on issues surrounding bankruptcy, we assume that if $X_1^h$ is realized, the firm repays its creditors, no assets remain in the firm, and the game ends at that point. If the
bad outcome is realized, the firm is illiquid and thus files for bankruptcy. When the bad outcome is realized, the firm may still have assets-in-place, and a new project that requires investment of new funds.

When the firm files for bankruptcy protection it can either be liquidated (the new project is cancelled and the assets are sold to pay creditors) or be given a chance to reorganize (the new project is funded). The piecemeal liquidation value of the firm’s assets-in-place, denoted $L$, consists of two components: the assets that are necessary for the firm’s reorganization, whose (possibly random) value is denoted by $L^i_n$, and those that are replaceable, with (possibly random) value $L^i_r$, so that $L = L^i_n + L^i_r$. The liquidation values of the necessary and replaceable assets are independent and have a binary distribution, with $L^i_n \in \{L^h_n, L^l_n\}$, where $L^h_n > L^l_n$ and $\Pr(L^i_n = L^h_n) = \lambda$, and $L^i_r \in \{L^h_r, L^l_r\}$ where $L^h_r > L^l_r$ and $\Pr(L^i_r = L^h_r) = \gamma$.

Replaceable assets are assets such as accounts receivable and other cash-equivalents, which may be essential to keep the firm running, but need not be provided by a specific source. We assume that replaceable assets can always be bought in a competitive marketplace at their liquidation value. Necessary assets are assets such as unique production facilities, intangible assets such as patents and trademarks, or inventory stocks, which are critical to the firm’s ongoing business but can not be replaced easily without substantial cost or delay. For example, if the inability to ship inventory to a customer in a timely fashion damages a firm’s reputation substantially, it may result in an eventual liquidation. In such circumstances, even if the inventory is not a unique product, it may be necessary for the firm to have immediate access to it in order to reorganize successfully. Unlike replaceable assets, we assume the necessary assets must be in the firm’s control if it seeks to reorganize. We assume that it is prohibitively difficult to write a contract that conditions creditors’ rights on $L^i_n$ or $L^i_r$, since these values will not be realized if the firm continues; this makes them imperfectly observable by a court. We assume, however, that $L^i_n$ and $L^i_r$ will be observable to all contracting parties at period one.

Continuation requires a fixed additional investment of cash and the necessary assets. We assume the firm’s existing creditors are passive creditors; thus, their claims cannot be renegotiated and the required continuation investment must come from an outside debtor-
in-possession (DIP) lender, who operates in a competitive lending market.\textsuperscript{8} We assume that managers have a bias toward continuing the firm’s operations, so the firm will always reorganize if it can find the required funds. If the firm reorganizes in bankruptcy, it pursues the new project which yields a random cash flow at period 2 of $X^h_2$ with probability $p_2$ or $X^l_2 < X^h_2$ with probability $1 - p_2$. The parameter $p_2$ summarizes the going-concern value of the firm; only the distribution of this variable is known as of period zero, which for simplicity is distributed uniform over the interval $[p^l_2, p^h_2]$. As with the liquidation values, we assume that contracts cannot be written on $p_2$, which is observed by only the manager and the DIP lender at period one.\textsuperscript{9}

The required additional cash investment is denoted by $K$, so that when the firm has replaceable assets (cash and receivables) in the bankruptcy estate worth $L^r_i$, it needs to obtain $K - L^r_i$ from outside investors and have control of the necessary assets in order to continue.\textsuperscript{10} For simplicity, we assume that $K - L^r_i > 0$, so that the firm always requires outside cash to continue. Figure 1 illustrates the timeline of the model.

We restrict attention (without loss of generality) to outside finance that has priority over the owner-manager in the event of default; thus the manager will not receive any cash if the first period project fails, regardless of whether the firm reorganizes.\textsuperscript{11} Even though the creditors will bear the losses from inefficient investment ex-post, they will anticipate this and demand ex-ante compensation through higher $F$. In equilibrium, the manager will bear the costs of inefficiency. Given these assumptions, the owner-manager’s maximization problem in period zero is simply to minimize $F$, the total amount owed to creditors following a success, since the manager’s payoff is $p_1(X^h_1 - F)$. This is accomplished by choosing capital structure in a way that minimizes the expected losses from inefficient investment decisions

\textsuperscript{8}In order for the model to work, we require only that the DIP lender is not the only pre-petition lender so that he does not internalize the entire value of the existing debt; this will be sufficient to generate excess continuations.

\textsuperscript{9}Assuming that the DIP lender has better information than other creditors is motivated by patterns in practice; DIP lenders are usually active creditors such as banks that often have prior relationships with the firm.

\textsuperscript{10}We assume that all assets are either perfectly replaceable (can be bought with cash in a competitive marketplace) or necessary (can be obtained from another source only at a very costly price). In reality, of course, the distinction between necessary and replaceable assets is not as polar as we present it here.

\textsuperscript{11}Even though such contracts are not \textit{uniquely} optimal here, they are optimal in most settings.
in bankruptcy.\footnote{We should note that we do not explicitly include a managerial private benefit of continuation, as in many models of capital structure. Introducing such private benefits would affect the problem only slightly; while the capital structure decision would similarly seek to guarantee ex-post efficiency, this might result in more continuations being efficient since the efficiency of continuation would also take into account the managerial private benefits.}

\section*{2.1 Financing Instruments}

We will consider four types of fixed income instruments the firm can issue to creditors in exchange for cash: unsecured debt, secured debt, leases, and asset-backed securities. We describe the properties of each of these instruments in turn, focusing on their respective rights in bankruptcy.\footnote{Given that the main goal of the paper is to compare ABS to other securities based on their treatment in bankruptcy, we cannot adopt a mechanism design approach and solve for optimal contracts. Thus, we necessarily restrict our analysis to existing contracts whose treatment in bankruptcy can be realistically characterized.}

**Equity** is junior to all other claims in bankruptcy. For simplicity, we assume that only the manager holds equity, which will always receive nothing in any bankruptcy outcome and will only be paid if the first period project succeeds.\footnote{While deviations from absolute priority in favor of equity are well-documented in bankruptcy, they are becoming increasingly rare (Baird and Rasmussen (2004)).}

**Unsecured debt** is senior to equity but junior to secured debt. Unsecured debt is also junior to the DIP lender. Unsecured creditors are subject to the automatic stay; thus, they cannot force the firm to liquidate if it can obtain DIP financing.

**Secured debt** is senior to unsecured debt and is (partially) senior to the DIP lender up to the liquidation value of the collateral. If the face value of the secured claim exceeds the value of the collateral, the remainder is treated as unsecured debt. Because secured creditors are also subject to the automatic stay, they cannot seize their collateral if the court determines that they receive *adequate protection*; this standard is subject to court discretion. As we will discuss in detail in Section 4, this may result in secured creditors receiving less than the value of their collateral.

**Leases** provide the firm with a call option on the underlying asset. If the firm assumes the lease, it must make the contractually specified repayment $F_L$ in full. Thus, leases are senior to DIP lenders and unsecured creditors. If the repayment is made, the lessor cannot
seize the underlying asset. If the firm rejects the lease, the lessor seizes the underlying asset and thus receives its liquidation value. Any difference between the face value $F^L$ and the realized liquidation value is treated as unsecured debt.

**Asset-backed securities (ABS)** involve a sale of the underlying assets to an SPV in exchange for cash. The SPV’s outside investors have debt and equity claims on the SPV, but not on the firm.\(^{15}\) We assume the SPV is always run in the interests of its outside investors (i.e. it is independent from the firm). Since the underlying assets are sold, they are not subject to the automatic stay. Thus, the SPV investors control the assets and are senior to all other claims on the firm up to the value of the assets. When the firm defaults, the SPV may sell the assets back to the firm at a price which maximizes the returns of the SPV investors. We assume these investors are arms-length investors, so they do not observe the firm’s going-concern value at period two, but do observe the liquidation value of the collateral.

We will now focus on the second period problem, when the firm enters bankruptcy. In order to understand the features of each of the securities above and to understand their effects on investment incentives in bankruptcy, we introduce each of them separately in the following sections. We then proceed to a discussion of optimal capital structure, in which multiple securities can be issued, in Section 4.3.

### 2.2 Unsecured Debt Only: The Second Period Problem

To generate some intuition about the impact of debtor-in-possession financing on investment, we start with the case where the firm finances itself entirely with unsecured debt. As we will see, this capital structure will be strictly sub-optimal, because it results in excessive continuations. This occurs because the ability to dilute unsecured creditors by issuing senior claims makes investment relatively attractive to the DIP lender/manager coalition.

Recall that when the firm enters bankruptcy, it can either be liquidated or reorganized.\(^{15}\) In practice, the firm may choose to *overcollateralize* the SPV. The firm retains a residual claim on the sold assets, so that after the SPV’s debt investors are paid in full, the firm receives the remainder. This equity tranche serves as a cushion to absorb any shortfalls in the cash flows the assets generate. We do not model this explicitly because overcollateralization is not optimal in our model. We discuss the reasons for this in section 3.
If it is liquidated, the assets in the estate are worth \( L = L_r^j + L_n^j \). If the firm reorganizes, it requires an additional cash input of \( K - L_r^j \). Thus, the going concern value of the firm is \( p_2 X_2^h + (1 - p_2) X_2^l - (K - L_r^j) \). We define the difference between the going-concern and liquidation values of the firm to be the *going concern surplus*. Continuation will be efficient if and only if the going concern surplus is positive (we will refer to this inequality as the “*efficiency condition*”).

\[
p_2 X_2^h + (1 - p_2) X_2^l - K - L_r^j \geq 0
\]  

(1)

To make the problem interesting, we assume that for some \( p_2 \), continuation is always efficient \((p_2^h X_2^h + (1 - p_2^h) X_2^l - K - L_n^h > 0)\) and for some \( p_2 \), liquidation is always efficient \((p_2^l X_2^h + (1 - p_2^l) X_2^l - K - L_n^l < 0)\). When the DIP lender is willing to participate, he lends \( K - L_r^j \) and takes a debt claim with face value \( F^D \). Following the rules of Chapter 11, the bankruptcy court allows the DIP lender to be senior to the existing unsecured creditors.

The unsecured creditors’ payoff in continuation is therefore \( \max\{X_2^j - F^D, 0\} \) and the DIP lender’s payoff is \( \min\{F^D, X_2^j\} \), where \( j \in \{l, h\} \).

In this scenario, the DIP lender’s participation constraint (which we refer to as the “*continuation condition*” since it determines whether or not the firm is able to reorganize) is given by

\[
p_2 X_2^h + (1 - p_2) X_2^l - (K - L_r^j) \geq 0
\]  

(2)

since the firm can offer the DIP lender a face value as high as \( F^D = X_2^h \).\(^{16}\)

In comparing the efficiency and continuation conditions, it is straightforward to verify that continuation will always occur when it is efficient. On the other hand, inefficient continuations may occur if (2) is satisfied but (1) is not. This is the familiar overinvestment problem captured in Gertner and Scharfstein (1991) and White (1989), that results from senior financing in bankruptcy. In such a situation, continuation occurs despite being inefficient, because the DIP lender is able to transfer sufficient wealth from existing unsecured creditors.

\(^{16}\)In practice, of course, the court can limit the interest rate the firm offers the DIP lender if it is excessive. This is of no consequence here, however, since competition limits the profits earned by the DIP lender to zero.
creditors through dilution of their claims. Inefficient overinvestment is more likely to occur when \( L_j^t = L_r^h \), since the DIP lender’s required investment is smaller. In essence, the DIP lender uses more of the firm’s existing assets (which would otherwise be paid out to unsecured creditors) to support the reorganization. Inefficiency is also more likely to occur when \( L_n^j = L_n^h \); in this case, liquidation of the necessary assets yields a higher payoff, which the DIP lender does not internalize. Since the DIP lender always earns zero profit in equilibrium, the unsecured creditors’ ex-post gain/loss relative to liquidation is the going concern surplus \( p_2X_2^h + (1 - p_2)X_2^l - K - L_n^j \).

We now turn to the effects of securitization, which can limit the excess continuations problem by guaranteeing the seniority of existing creditors.

3 The Effect of Securitization

When the firm undertakes securitization at period zero, assets are sold to an SPV in exchange for cash provided by outside investors who receive in return ABS issued by the SPV. Securitization is commonly referred to as a left-hand-side balance sheet financing method. Instead of increasing both sides of its balance sheet when debt is issued, the firm obtains the required cash by selling existing assets on its balance sheet for cash. While the accounting for these transactions is not relevant for our model per se, the legal ownership of the securitized assets will be crucial because it will affect the ability of the firm to obtain DIP financing. Securitization affects the size of the bankruptcy estate at period 1 in case the first project fails, and by extension, the funds the firm must raise in order to continue.\(^\text{17}\)

We now proceed to analyze the effect of securitization on ex-post efficiency at bankruptcy. The effect of securitizing will depend greatly on whether the assets are replaceable or necessary.

\(^{17}\text{When the firm undertakes securitization, as opposed to debt issuance at period 0, it effectively breaks down its balance sheet into two separate balance sheets - one that will be part of an eventual bankruptcy estate and another which will be insulated from a bankruptcy procedure. When true sale is achieved, the firm cannot use the assets on the SPV’s balance sheet in order to pursue the second project since those assets are not considered part of the bankruptcy estate. In order to continue the firm therefore needs to obtain larger amount of cash infusion from outside lenders, which decreases the likelihood of obtaining the sufficient amount, and as a result, the likelihood of continuation.}\)
3.1 Securitization of Replaceable Assets

We begin by analyzing a firm that has only replaceable assets \( L_n^r = 0, \lambda = 0 \). When the firm securitizes part of its assets, the required outside investment at bankruptcy, as noted above, also depends on the level of securitization. Assume the firm securitizes a fraction \( \varphi \) of its asset base. In order to continue at bankruptcy, the firm will then need to raise \( K - (1 - \varphi)L_i^r \) to continue. The continuation condition becomes

\[
p_2 X_h^r + (1 - p_2) X_l^r - (K - (1 - \varphi)L_i^r) \geq 0
\]  

(3)

Recall that in choosing the capital structure at date zero, the owner-manager seeks to guarantee ex-post efficient outcomes if possible, since this minimizes his repayment conditional on success. With no necessary assets, the efficiency condition is

\[
p_2 X_h^r + (1 - p_2) X_l^r - K \geq 0
\]  

(4)

It is easy to verify that the two conditions are equal if and only if \( \varphi = 1 \). In other words, when the firm securitizes all its assets-in-place, continuation occurs if and only if it is efficient. This is stated formally in the following proposition:

**Proposition 1** When the firm has no necessary assets, it is optimal to securitize all assets-in-place (i.e. securitized assets equal \( L_i^r \)), and bankruptcy outcomes are always ex-post efficient.

**Proof.** See Appendix. ■

As proposition 1 affirms, setting the level of the assets sold to the SPV equal to \( L_i^r \) (which amounts to securitizing all the firm’s assets-in-place)\(^{18}\) guarantees efficient outcomes ex-post. In essence, the transaction allows the firm to separate its growth option from its existing asset base, which guarantees that the decision to adopt the new project is not subject to investment distortions created by the priority rules in bankruptcy. When the firm securitizes all its assets-in-place, outside investors must provide the entire required investment \( K \) to continue,

\(^{18}\)Note that the assumption of no necessary assets in this section refers to physical assets only. This does not rule out that firm may have necessary intangible assets such as human capital, reputation, etc. that can result in the firm having a growth option despite having no tangible assets on its balance sheet.
and they can be promised all the proceeds. This gives the firm and the DIP lender the proper incentives with respect to the continuation decision.\footnote{In terms of the first period problem, the assumption of competition pins down the solution. If $I_0$ is greater than the ABS investors’ expected payoff, the ABS investors contribute initial capital such that they break even, and we assume the remainder is contributed by unsecured creditors. Second, if $I_0$ is less than this expected payoff to ABS investors, they will contribute more than $I_0$, and the manager will pay himself a dividend equal to the excess.}

While securitizing all of the firm’s existing assets might seem to be a non-conventional idea, this phenomenon has been growing in importance. Whole Business Securitization (WBS) involves the transfer of the entire assets of the firm, or the rights to the future cash flows generated by these assets, to a separate legal entity which in turn issues claims for outside investors backed by the assets. An example of WBS\footnote{In the U.S. such transactions are sometimes referred to as “operating company securitizations.”} is a deal executed by Triarc Companies, a holding company that, through its subsidiaries, is the franchisor of Arby’s restaurants. Every Arby’s restaurant is owned and operated by an independent franchisee that pays both franchise fees and royalties. Triarc structured a transaction where the rights for all the future cash flows stemming from the franchise fees and royalties paid by Arby’s franchisees were transferred into a separate legal entity that financed such transactions with funds raised from various institutional investors.

In comparing the result in Proposition 1 to securitization patterns in practice, one additional feature is worthy of mention. ABS issuances are often over-collateralized, such that the firm actually retains the equity position in the SPV. One reason for this structure is to eliminate adverse selection problems that arise when the firm has superior information about the quality of the sold assets (Leland and Pyle (1977)). An equity stake in the SPV may also alleviate a moral hazard problem that arises if the firm is required to monitor and service assets it does not own (see Pennacchi (1988), Riddiough (1997)).

Because our goal is to focus on the impact of bankruptcy remoteness in ABS transactions, we do not explicitly include these moral hazard and adverse selection problems that may occur in practice. Proposition 1 is relevant to the issue, however, since it demonstrates that retention of an equity position to solve these problems can come with a cost; namely, that ex-post efficiency at bankruptcy can suffer. When the firm is entitled to the residual funds from the SPV’s assets, the firm might use them to support a reorganization, to the detriment of
ex-post efficiency.\textsuperscript{21} We expect, then, that the firm will trade-off these inefficiencies, or look for alternatives to overcollateralization to solve adverse selection and moral hazard problems. This underscores the importance of credit rating agencies in evaluating the backing assets and estimating their payment capability. Since rating agencies can alleviate adverse selection problems by generating higher quality information about the underlying assets, there is less need for the firm to retain the SPV’s equity position and capital structure can be used to better alleviate the continuation bias inherent in the bankruptcy law.

This intuition can also help explain a trend over time in securitization practice toward lower levels of overcollateralization. As the securitization market has developed, and longer histories of performance of securitized assets are available, the costs of asymmetric information in securitization issues are plausibly decreasing over time. This implies that the firm can focus less on issuing safe outside claims, and more on the commitment role of ABS in preventing inefficient bankruptcy outcomes. Our model suggests that this is achieved by securitizing more of the firm’s replaceable assets.

3.2 Securitization of Necessary Assets

Proposition 1 shows that to achieve ex-post efficiency in bankruptcy, the firm should securitize all its assets when the assets are entirely replaceable. This allows the firm to commit to investing in bankruptcy if and only if it is efficient. We now show that the situation is quite different when the firm has also necessary assets. Since the firm can easily recover for the loss of its replaceable assets with outside financing, and leaving excess assets in the firm creates ex-post inefficiencies, the firm will continue to securitize all its replaceable assets, therefore requiring a minimum of $K$ dollars of DIP financing in case of bankruptcy. In contrast, securitizing of necessary assets forces the firm to find a way to gain access to those particular assets at bankruptcy, rather than simply seek outside financing commensurate with their value.

Recall that we define necessary assets as those the firm needs in order to pursue its

\textsuperscript{21}In such a case, assuming the firm securitized all its assets-in-place, the continuation condition becomes $p_2 X_h^2 + (1 - p_2) X_l^2 - K + \theta \geq 0$, where $\theta$ is any residual funds from the SPV, and inefficient continuations might occur similar to the situation discussed in section 2.2.
ongoing projects, and are too costly to replace with substitutes. Since securitization is effectively a sale of an asset, the SPV obtains ownership rights to the asset. This implies that in bankruptcy, the SPV has legal rights of control; if the firm needs these assets to reorganize, it must repurchase them from the SPV, which seeks to maximize the returns of its lenders. This may lead to inefficient outcomes if the resulting bargaining is subject to asymmetric information. We model this inefficiency below.\footnote{In addition to ex-post inefficiencies due to asymmetric information in bargaining, the familiar problem of ex-post holdup reducing ex-ante firm-specific investments (Grossman and Hart (1986)) may also be relevant here. We focus on the bargaining breakdown because it was a salient problem in the LTV bankruptcy.}

We assume that the SPV (or the trustee that acts on behalf of its investors) is not informed about $p_2$, and hence has incomplete information about the firm’s going concern value. Knowing that the firm requires the necessary securitized assets, the SPV makes a take-it-or-leave-it offer to the firm that maximizes its expected surplus. If the firm rejects the offer, it proceeds to liquidation.

Since the SPV investors attempt to capture some of the (expected) going concern surplus, the firm will be asked to repurchase the necessary asset at a price that is higher than its liquidation value.

The timeline of the bargaining process is as follows:

1. SPV makes an offer to sell the necessary asset back to the firm for $M^j$ dollars where $j \in \{l, h\}$. This will depend on the liquidation value of the necessary assets.

2. The DIP lender decides whether to lend $K + M^j$ to the firm in exchange for a debt claim $F^D$. If not, the firm liquidates.

The SPV investors choose $M^j$ optimally to maximize their expected surplus. Recall that $p_2$ is distributed $U[p^l_2, p^h_2]$.

The SPV’s problem is the following:

$$\max_{M^j} \frac{p_2(M^j) - p^l_2}{p^h_2 - p^l_2} L^j_n + \frac{p^h_2 - p_2(M^j)}{p^h_2 - p^l_2} M^j$$

(5)

where $p_2(M^j)$ solves $p_2 X^h_2 + (1 - p_2) X^l_2 = M^j + K$.\footnote{In addition to ex-post inefficiencies due to asymmetric information in bargaining, the familiar problem of ex-post holdup reducing ex-ante firm-specific investments (Grossman and Hart (1986)) may also be relevant here. We focus on the bargaining breakdown because it was a salient problem in the LTV bankruptcy.}
Solving this problem yields the SPV investors’ optimal offer price to the firm:

\[ M^{j*} = \frac{1}{2} (p^h_2 X^h_2 + (1 - p^h_2) X^l_2 - K) + \frac{1}{2} L^j_n \]

Since the going concern surplus is always positive when \( p_2 = p^h_2 \), \( M^{j*} > L^j_n \). Analyzing this offer we can see that \( M^j \) is increasing in \( p^h_2 \) but not \( p^l_2 \). Thus, for a given expected continuation value, a higher variance due to greater uncertainty increases the offer price of the SPV. As the next proposition shows, this will result in excessive liquidations.

**Proposition 2** If the firm securitizes necessary assets, there exist \( p_2 \in [p^l_2, p^h_2] \) such that \( p_2 X^h_2 + (1 - p_2) X^l_2 - K - L^j_n > 0 \) and \( p_2 X^h_2 + (1 - p_2) X^l_2 - K - M^{j*} < 0 \); the firm liquidates despite continuation being efficient.

**Proof.** See Appendix. ■

Inefficient liquidations occur because it is too costly for the firm to continue without its necessary asset, and in an attempt to extract maximum surplus for its investors, the SPV offers too high a price.

The LTV Steel bankruptcy, while providing a natural experiment on the impact of bankruptcy remoteness, also illustrates the particular problems a firm may face when it securitizes necessary assets. Prior to filing for bankruptcy, LTV had two securitization structures in place. Its accounts receivable were sold to an SPV which was financed primarily by Abbey National Bank, and its inventory was sold to an SPV financed primarily by Chase Manhattan Bank. As LTV moved closer to the bankruptcy filing, it began negotiations with these banks, but the negotiations subsequently broke down. Needing control over its working capital, LTV filed for Chapter 11 in December, 2000 and asked the bankruptcy court for permission to include the securitized assets inside the bankruptcy estate. Their argument was predicated on the notion that LTV could not continue operating without the assets, and that granting the SPV control over them would result in a costly liquidation.\(^{23}\) The bankruptcy court, siding with LTV, issued an interim cash collateral order that allowed the

\(^{23}\) In a brief to the bankruptcy court, LTV claimed that the SPV investors “have attempted to ‘opt-out’ of the United States Bankruptcy Code to capture the most valuable assets of the Debtors to dispose of as they see fit, at a painful cost to the Debtors’ employees, unsecured creditors and shareholders.”
firm to use the receivables and inventory to support its ongoing operations. The decision created substantial uncertainty in the ABS market about the ability to achieve bankruptcy remoteness, which we use to identify the value of bankruptcy remoteness in section 5.

The LTV example also illustrates several of the features captured in our model. First, the time inconsistency of managerial behavior is apparent. LTV securitized its working capital to take advantage of the lower cost of financing that follows from bankruptcy remoteness, but later tried to undermine the securitization in order to continue operating. Second, unlike a more traditional securitization of receivables only, LTV required consent from its securitization lenders, who would have legal control over both receivables and inventory in the event of bankruptcy. Bargaining was not able to produce a speedy resolution prior to its Chapter 11 filing, and the breakdown forced LTV to seek help from the bankruptcy court.

LTV is not the only example of a securitization of necessary assets that faced potential trouble in bankruptcy. Days Inn, a hotel chain, filed for Chapter 11 in the late 1980s. In a WBS transaction, Days Inn had securitized its franchise fees (replaceable assets in our model) but along with it, also sold its trademarks (necessary assets) to the SPV. In bankruptcy, Days Inn found a willing buyer, whose willingness to purchase the company was conditional on owning the company trademarks. In this case, the company was able to reach a settlement with the trustee of the SPV that enabled the bankruptcy sale to take place, but the market has apparently taken notice of the problems associated with securitizing necessary assets.\(^{24}\)

With these results in hand, we expect that other existing securities may be preferred when ex-post holdups are possible due to the existence of necessary assets. In the following section we consider two other securities which limit the control rights of the lender in bankruptcy: secured debt, which substitutes court control for creditor control, and leases, which give the firm an option to keep the necessary asset at a pre-determined price. We compare these securities to ABS and each other, and generate comparative statics that can predict their usage.

4 Substitutes for ABS: Secured Debt and Leases

4.1 Secured Debt

As we noted at the outset, some similarities exist between ABS and secured debt. In some sense, because outside investors are given unrestricted rights to the underlying assets in bankruptcy, ABS most resemble the traditional view of debt in classic models such as Hart and Moore (1994). As we saw in the previous section, however, the unchecked power of the ABS investor can result in inefficient liquidations when control of the underlying assets is necessary for the firm’s ongoing projects. Secured debt, on the other hand, restricts the lender’s control rights in bankruptcy by substituting court-determined protection for creditor control. While this protection, through the automatic stay, is unlikely to improve upon outcomes when the underlying assets are replaceable (since ABS is optimal), we might expect that this can have some benefits in preventing creditor holdup when assets are necessary.

While it is difficult to completely characterize the treatment of secured creditors in bankruptcy, several features are crucial for our analysis. First, seniority for a secured creditor is based on the value of the collateral, not the face value of their claim. When a secured creditor’s claim exceeds the value of the collateral, the remainder of the claim is considered unsecured and can thus be primed by a DIP loan. Second, given existing practice in Chapter 11, secured creditors are not guaranteed the same payoff as they would receive if they were allowed to claim their collateral. While secured creditors are allowed compensation for the depreciation of the collateral (through adequate protection payments), they are not fully compensated for the time value of money lost during the reorganization. In this sense, secured creditors’ claims are diluted by the time delay inherent in confirming a plan of reorganization. The law also allows for the possibility of “priming liens” that would

\[11 \text{ U.S.C. } \S 361. \text{ See also U.S. Bankruptcy Judge (S.D.N.Y) Robert D. Drain, A Short Summary of Chapter 11 of the United States Bankruptcy Code (2003).}
\]

\[26 \text{ Oversecured creditors are entitled to post-petition interest, but this does not increase the overall “supply” of seniority; these payments would be made only up to the value of the collateral. Thus, the overall value that is protected from dilution by the DIP lender is thus bounded above by the value of the collateral. See Ayer and Bernstein (2002).}
\]

\[27 \text{ Ayotte and Skeel (2004) find empirical evidence that secured creditors are important drivers of venue choice in bankruptcy, and exhibit a strong preference for Delaware, which produces significantly faster reorganizations.}
\]
allow a DIP lender to trump the secured creditor’s priority, though this is not used often in practice.

Taken in full, existing rules and practice in Chapter 11 suggest that the guaranteed seniority of secured creditors is less than the liquidation value of their collateral on the bankruptcy date. To model this simply, we assume that (if all the assets are secured) in order to continue the secured creditors must receive a claim with expected value \((1 - \delta) (L_n^j + L_r^j)\), the realization of the liquidation value scaled down by a dilution parameter \(\delta \geq 0\). Given that secured creditors lose protection based on the time value of money, it is sensible to assume that the amount of dilution suffered by the secured creditors, \(\delta (L_n^j + L_r^j)\), is proportional to the liquidation value. Under these assumptions, the continuation condition is as follows when all assets-in-place are secured\(^28\):

\[
p_2 X_2^h + (1 - p_2) X_2^l - (1 - \delta) (L_n^j + L_r^j) - (K - L_r^j)
= p_2 X_2^h + (1 - p_2) X_2^l - K - L_n^j + \delta (L_n^j + L_r^j) \geq 0
\]

Note that when \(\delta = 0\), the continuation condition is once again identical to the efficiency condition and ex-post efficiency is obtained. If \(\delta\) is positive, then financing with secured debt leads to excess continuations, which is greater when the liquidation value of the assets is high. On the other hand, we can see the potential benefit of secured debt relative to ABS, namely its ability to prevent inefficient creditor holdups. If the court-based valuation can exactly match the secured creditor’s claim to the liquidation value of the collateral (i.e. \(\delta = 0\)), then ex-post efficiency can always be achieved. Since the secured creditor does equally well under liquidation and continuation, the DIP lender can not be persuaded to invest by using the dilution proceeds from existing creditors. As the value of \(\delta\) increases, the corresponding benefits of secured debt are commensurately reduced. Note also that the costs/benefits of secured debt do not depend on whether the assets are necessary or replaceable.

The comparison of ABS and secured debt reveals that secured debt has the potential to

\(^{28}\)If only unsecured and secured debt are allowed, securing all assets-in-place, rather than leaving some assets unsecured, would be optimal.
alleviate the problems introduced by securitization when the assets are necessary, but such potential crucially depends on the bankruptcy treatment of secured debt. However, secured debt is not the only senior financing instrument that can be used to substitute for ABS. In the next section we consider the bankruptcy treatment of leasing contracts and their effects on investment incentives.

4.2 Leases

While secured debt is usually perceived as the highest priority claim in bankruptcy, lessors implicitly receive a higher level of protection. A leased asset is not automatically excluded from the bankruptcy estate if the debtor/lessee convinces the court that the asset is necessary for the continued operation of the firm. In this sense, the bankruptcy treatment is similar to that of collateral backing a secured claim. However, if the debtor keeps the leased asset in the bankruptcy estate, thereby “affirming” the lease, unlike the case of secured debt, it must pay the lessor the contractual payments during and after the bankruptcy case. Alternatively, if the debtor “rejects” the lease, the lessor can foreclose on the asset. In other words, the law protects lessors from adjustments in their contractual rights without their approval.\footnote{The bankruptcy code grants the debtor a (potentially extendable) 60-day period to make a decision about whether to assume or reject the lease, and contains subtle differences in the treatment of personal property leases and real property leases (see 11 U.S.C. §365(d)(3) and §365(d)(10)). These subtleties are unlikely to be consequential for the general treatment of leases illustrated in our model.}

Recall our assumption that $L_j^i \in \{L^l_n, L^h_n\}$, where $L^h_n > L^l_n$ and $\Pr(L_n = L^h_n) = \lambda$ and $L^j_i \in \{L^l_r, L^h_r\}$ where $L^h_r > L^l_r$ and $\Pr(L_r = L^h_r) = \gamma$. The efficiency condition, as before, is given by

$$p_2 X^h_i + (1 - p_2) X^l_i - K - L^j_n > 0$$

(6)

where $j \in \{l, h\}$.

If the firm uses a lease to finance its assets, it must make the contractually specified payment $F^r_i i \in \{r, n\}$ in order to be able to continue using the assets. If the firm rejects the lease, the lessor repossesses the collateral. If the collateral is a necessary asset, this leads to liquidation of the firm, since by definition the firm must have control of the necessary
assets to take advantage of its investment opportunity. Rejection of a lease on replaceable assets does not necessarily lead to liquidation, but increases the amount of cash required from outside investors. The continuation condition under leasing therefore becomes

$$p_2X^h_2 + (1 - p_2)X^i_2 - (K + F^L_n) + (L^r_i - F^L_r)^+ \geq 0$$

(7)

The DIP lender can receive up to the entire cash flow from the project $p_2X^h_2 + (1 - p_2)X^i_2$, but must contribute an additional $K$ and assume the lease on the necessary asset at a cost of $F^L_n$. If the value of the replaceable assets makes assumption of the lease optimal (which occurs when $L^r_i - F^L_r$ is positive), then the required cash contribution is commensurately less. Comparing the efficiency and continuation conditions under lease financing, we observe that inefficient continuations (liquidations) can occur when $F^L_n - (L^r_i - F^L_r)^+$ is less than (greater than) $L^i_n$.

Given that all the assets-in-place are financed by leases, we can ask what the optimal contracts $\{F^L_r, F^L_n\}$ would look like. This is summarized in the next lemma.

**Lemma 3** The optimal lease policy sets the lease payment on the necessary assets, $F^L_n$, equal to the expected liquidation value $E(L_n)$. The lease payment on the replaceable assets, $F^L_r$, is set such that the lease is always rejected; i.e. the optimal $F^L_r$ is any value such that $F^L_r \geq L^i_r$.

**Proof.** See Appendix.

The intuition for the result is as follows. In setting the lease payments, the firm would like to commit to a policy that guarantees efficient investment, which requires setting $F^L_n - (L^r_i - F^L_r)^+$ as close to $L^i_n$ as possible in expected terms. Since the liquidation values $\{L^i_j, L^i_n\}$ are not known when the contract is written, randomness in the liquidation values leads to greater investment inefficiency. Setting $F^L_r \geq L^i_r$ is optimal because it eliminates any noise caused by randomness in the replaceable assets. Note that a lease that is never assumed in equilibrium is equivalent to securitization, since the firm has no remaining rights to the asset.

---

30 For simplicity of exposition, we do not model renegotiation of leases. Under any reasonable specification of a renegotiation game, we expect that the main results concerning leases will hold, namely that: a) leases offer more protection to the firm than ABS, due to the call option, and b) leases provide more creditor protection but less flexibility than secured debt, because the bankruptcy court is not involved.
With this result in hand, the lease payment on the necessary assets is set so that the expected loss from inefficient continuations and liquidations is minimized. This is accomplished by setting $F_n^L$ between the two possible liquidation values of the necessary assets. When the high liquidation value is realized, inefficient continuations can occur, and when the low liquidation value is realized, inefficient liquidations may occur.

Comparing with our earlier analysis, leases have an advantage over secured debt and ABS in the ability to commit to an efficient balance between creditor and firm rights in bankruptcy. The value of secured creditors’ claims is affected by the bankruptcy procedure to the detriment of creditors (provided that $\delta > 0$), which leads to inefficient continuations. The value of ABS is determined by ex-post bargaining, to the detriment of the firm, which leads to inefficient liquidations. With necessary assets, the ability to commit to preventing ex-post opportunism makes leasing valuable. This commitment comes at a cost, however, since the required repayment does not adjust to new information about the liquidation values realized after the contract is written. This inflexibility can also result in ex-post inefficient outcomes. In this sense, leases are inferior to secured debt, which uses the discretion of the bankruptcy judge to match the secured creditor’s claims to the realized liquidation value of the assets.

With respect to replaceable assets, our analysis confirms that leases can do no better than ABS, since there is no cost to providing maximal creditor protection for these assets. Giving the firm a valuable option to purchase assets at a pre-determined price is never optimal, since replaceable assets will always be available at a price that reflects their opportunity cost. Adding this option would merely add noise to the continuation decision which an optimal contract seeks to avoid.

### 4.3 Optimal Capital Structure

In this section, we briefly summarize the costs and benefits of the securities we have analyzed, and then provide some comparative statics on optimal capital structure.

**Asset-backed securities**

**Benefit: Maximal creditor protection.** The bankruptcy remoteness of the securitized assets gives creditors control rights that prevent dilution in bankruptcy. ABS is most
valuable for *replaceable assets*, where there are no costs to full creditor control.

**Cost:** *Bargaining failure.* When assets are *necessary*, giving creditors control rights leads to bilateral bargaining which can be inefficient under asymmetric information. The attempt by creditors to extract more surplus from the firm leads to inefficient liquidations.

**Secured debt**

**Benefit:** *Flexibility.* The judicially-supervised bargaining process under Chapter 11 rules allows the secured creditor’s seniority to depend on the realized liquidation value of the assets. This flexibility can improve the efficiency of investment in bankruptcy.

**Cost:** *Dilution.* Under current law, secured creditors are not entitled to the same protection in reorganization as in liquidation; this distortion leads to inefficient continuations.

**Leases**

**Benefit:** *Dilution protection and balance.* Like ABS, lease contracts are not adjusted by the bankruptcy process, which protects creditors. Unlike ABS, the firm is given a call option on the assets, which limits creditor hold-up power.

**Cost:** *Inflexibility.* Unlike secured debt, the contract does not adjust to the realized liquidation value, which can produce inefficient over- and under-investment in equilibrium.

Having analyzed each of the components of the firm’s capital structure separately to generate intuition, we will now allow the firm to issue multiple securities in order to generate some comparative statics regarding optimal capital structure. We simplify the problem slightly by assuming that each asset type must be financed by one security. The next proposition summarizes our results.

**Proposition 4** *For the given parameter values, the following capital structures are optimal:*

a) When $L_n^h = 0$, $\lambda = 1$, the optimal capital structure is to securitize all existing assets.

b) As $\delta \to 0$, the optimal capital structure is to securitize all replaceable assets and issue secured debt backed by the necessary assets, with face value of at least $L_n^h$;

c) As $Var(L_n) \to 0$, the optimal capital structure is to securitize all replaceable assets and lease necessary assets with an option to assume the lease at a price $E(L_n)$.

**Proof.** See Appendix. ■
Part (a) of the proposition is a restatement of Proposition 1. Parts (b) and (c) point out the main costs and benefits of secured debt relative to leases. As the expected dilution of secured creditors falls, the flexibility benefit of secured debt dominates the commitment value of leases. As the variance of the liquidation value of the necessary assets falls, the cost of leasing disappears and contracts can be optimally set to produce efficient investment without the bankruptcy process. In all cases, it is optimal to securitize the replaceable assets, for which maximal creditor protection is optimal.

In summary, our theoretical analysis points to variations in creditor rights under bankruptcy law as an important driver of firms’ optimal capital structure decisions. An optimal capital structure balances control and cash flow rights between creditors and the firm in a way that minimizes the costs of inefficient investment choices in bankruptcy. Asset-backed securities are unique, particularly in comparison to secured debt contracts, in that they maximize ex-post protection of creditors in bankruptcy. If this distinction is relevant economically, we should expect to see competitive credit markets attach lower interest rates on ABS issuances compared to an equivalent contract structured as a secured loan. The LTV Steel bankruptcy provides an opportunity to examine this issue empirically.

5 Empirical Evidence

5.1 Motivation

To assess the value financial markets attach to bankruptcy remoteness, we utilize the natural experiment provided by the judge’s interim cash collateral order in the LTV Steel bankruptcy in late 2000. As described earlier, this decision cast significant doubt on the ability to legally isolate assets and ensure the insulation of ABS from a Chapter 11 procedure. While the interim decision did not become a binding legal precedent (LTV and its ABS lenders reached an out-of-court settlement before a final binding decision was made), the case and its potential ramifications reverberated across the securitization market. The Dow Jones Newswires, for instance, stated:

“The bankruptcy-remote vehicle structure, the backbone of the debt securiti-
Our empirical strategy makes use of the fact that the implications of the LTV decision should have affected some ABS issuers more than others. Specifically, asset-backed securities originated by insured depository institutions should not have been affected by the LTV case for two reasons. First, their insolvency procedure is governed by the FDIC, making these originators ineligible for Chapter 11. More importantly, FDIC receivership rules include a provision (§360.6), in place when the LTV bankruptcy occurred, which explicitly guarantees that securitized assets can not be recharacterized. No such provision exists in the U.S. bankruptcy code. For these reasons, ABS originated by insured depository institutions create an ideal control group to identify the value of bankruptcy remoteness to ABS investors.

This difference between the two types of securitizers naturally lends itself to a difference-in-differences empirical analysis. We measure the difference-in-differences of ABS spreads over maturity-matched swap rates for depository and non-depository securitizers in the six month period before and after the LTV filing. Provided that any other changes in the ABS market pre- and post-LTV affected both depository and non-depository ABS, our difference-in-differences estimator is intended to capture the pure effect of the uncertainty created by LTV on ABS spreads.

---

31 Feldheim, David, 2001, “LTV ruling challenges legal basis for securitizations”, Capital Market Report, Dow Jones Newswires, February 16, 2001. See also Final, Colin, 2001, “Testing the waters of US ABS”, Corporate Finance Magazine. We also examined several reports by major investment banks over the period, which expressed similar concerns as a result of LTV.

32 Specifically, 360.6(b) states: “The FDIC shall not, by exercise of its authority to disaffirm or repudiate contracts under 12 U.S.C. 1821(e), reclaim, recover, or recharacterize as property of the institution or the receivership any financial assets transferred by an insured depository institution in connection with a securitization or participation, provided that such transfer meets all conditions for sale accounting treatment under generally accepted accounting principles, other than the "legal isolation" condition as it applies to institutions for which the FDIC may be appointed as conservator or receiver which is addressed by this section.”
5.2 Data

We obtained data from SDC Platinum New Issues database on all public securitization transactions executed during the year centered around LTV bankruptcy filing. To focus attention on corporate securitizers, we exclude all securitized instruments issued by government sponsored enterprises (GSE) such as Federal Home Loan Mortgage Corporation (FHLMC, or Freddie Mac) and Federal National Mortgage Association (FNMA, or Fannie Mae.) Also excluded are firms that act as issuing intermediaries for other firms that do not tap the market directly. Most major investment banks maintain securitization conduits. However, as verified by consulting issuance prospectuses, the assets backing the securities issued by these conduits were not originated by the investment banks but instead were purchased from many different firms and then pooled together. Thus, we do not observe the identity of the “true” originators in these cases. Finally, we restrict our sample to triple-A rated securities, for which sufficient data is available. The SDC database includes a small and incomplete sample of lower-rated ABS, since these tranches are more often privately placed; we exclude these to avoid potential sample selection issues.

We record the securities’ yield-to-maturity at issuance, average life, issuance size and the identity of the originator. We consider ABS issued with fixed coupons.\textsuperscript{33} To control for yield-to-maturity variations related to shifts in the term structure, we calculate the ABS spread over the swap rate with the closest maturity to the ABS average life using daily swap rates obtained from Datastream.\textsuperscript{34}

To determine whether the originator is eligible for Chapter 11 or FDIC receivership, we examined the individual prospectuses for each issuance to determine the identity of the originator. In most cases, the prospectus explicitly identifies the potential risks to investors of either Chapter 11 or receivership, depending on the identity of the originator. Several of the prospectuses we examined in the post-LTV period explicitly mention the LTV case when discussing risks of originator bankruptcy; we present one such example in Appendix A. We also verified the status of the originator using a searchable directory of insured banks

\textsuperscript{33} Restriction of the analyzed dataset to include instruments issued with fixed coupons has also been common in recent empirical corporate bond studies. See, for example, Eom, Helwege and Huang (2004).

\textsuperscript{34} For a discussion why swap rates rather than Treasury rates are used as a benchmark by corporate issuers, see, for instance, Collin-Dufresne and Solnik (2001).
available on the FDIC’s website. Our final sample includes 585 issuances (tranches) where all data are available. Description of the data and summary statistics are provided in Table 4.

5.3 Results

To identify the effect of the LTV case on credit spreads, we regress ABS spreads on three dummy variables. The first dummy variable ("Post-LTV") equals one if the issuance occurs in the 6 month period after the LTV bankruptcy. The coefficient captures the average change in ABS spreads in the pre- and post-LTV periods due to macroeconomic or other influences. To the extent that such influences affect depository and non-depository securitizers equally, it should be picked up by this dummy. The second variable ("Non-depository") equals one if the originator is not an insured depository institution, thus making it eligible for Chapter 11. The coefficient on this variable captures differences in spreads between depository securitizers and non-depository securitizers, such as differential asset types, that are not due to the LTV effect. Of most interest to us is the dummy variable created by interacting the variables Post-LTV and Non-depository ("Post-LTV*Non-depository"). The coefficient captures the pure effect that the LTV bankruptcy had on spreads for Chapter 11-eligible securitizers. We report OLS regressions where the standard errors are corrected for potential clustering effects at the issuer level.

Table 5 reports the results under various specifications. The coefficient on the interaction dummy is economically large (between 26 and 29 basis points) in all specifications and statistically significant in all but the most basic regression with no controls (column (1)). In columns 2 through 5 we include a series of control variables that we expect to affect ABS spreads. We expect that issuance size, which acts as a proxy for liquidity, should reduce spreads, while longer maturity should increase spreads (John, Lynch and Puri (2003) and Longstaff, Mithal and Neis (2004)). We control for these effects by including linear and both linear and quadratic terms for issuance size and average life in columns (2) and (3), respectively. The coefficients on the control variables have the expected signs. Adding

\footnote{The website is http://www2.fdic.gov/idasp/main.asp}

\footnote{The issuer is the vehicle that issues ABS by a particular originator on a particular date.}
the control variables sharply decreases the standard error of the difference-in-differences coefficient but does not affect the magnitude greatly. In column (4) we add asset type dummies to control for variation in the type of assets being securitized, and in column (5) we replace asset type dummies with originator fixed effects. The magnitude and statistical significance of the LTV effect is robust to each of these specifications.

In summary, our results show that following the LTV bankruptcy filing, non-depository securitizers, which are more likely to be sensitive to the ramifications of this case, experienced a statistically and economically significant increase in their ABS issuance spreads relative to insured depository securitizers that were not Chapter 11 eligible. That result is consistent with our theoretical characterization of ABS, in that the avoidance of dilution in bankruptcy is valuable to creditors in a way that is observable in prices.

The empirical results also contribute to an understanding of a common justification for ABS. It is often argued that securitization allows firms to issue AAA rated securities “off the balance sheet”, making it possible to borrow at a lower rate than they could “on the balance sheet”. The fact that spreads increased sharply after LTV is an important indicator that bankruptcy treatment of securitization is a major explanatory factor for why these borrowing costs differ.

6 Discussion and Policy Implications

Having analyzed and compared the specific bankruptcy treatment of the financing instruments we consider in this paper, we are now ready to discuss the implications of our results for regulatory policy. Since the most novel financial technique we consider is securitization, which is also the focus of our model, we concentrate on discussing the prevailing and desired regulatory treatment of securitization in the context of bankruptcy.

We show in our model that when the underlying assets are replaceable, securitization can increase firm value by allocating cash flow and control rights in a way that cannot be replicated by other financing instruments. The distinction between ABS and secured debt, 37

37 In this specification, we do not report the “non-depository” dummy, which is rendered redundant by the originator fixed effects.
for example, depends crucially on complete separation of the securitized assets from the firm and their exclusion from the bankruptcy estate. As we noted above, such exclusion could be maintained only if a “true sale” is achieved and the bankruptcy court does not re-characterize the transaction as secured financing, resulting in the consolidation of the SPV’s assets into the firm’s bankruptcy estate. The data confirm that the protection to creditors afforded by ABS is indeed economically significant.

Addressing the concerns raised by the market in light of court decisions such as LTV, Congress considered adopting across-the-board “safe harbor” for structured finance transactions, by amending the federal bankruptcy code. The proposed amendment would have changed the definition of a bankruptcy estate to exclude all securitized assets, notwithstanding the fulfillment of state-level tests to determine the sale/secured loan characterization. Such “safe harbor” would also have prevented bankruptcy judges from re-characterizing a structured finance transaction as secured debt. The proposed amendments were brought before the Congress in 2001 but were rescinded a year later following the revelation of fraud at Enron, much of which involved SPVs (see Schwarcz (2003)). The current legal situation is thus still unclear. ABS investors cannot rely upon clear-cut federal regulation guaranteeing their insulation from the originator’s bankruptcy but rather have to navigate through a complicated and sometimes murky state regulation and case decisions.38 The prospects of securitized assets being forced to be a part of a bankruptcy estate, thus effectively losing the efficiencies we have identified, are therefore not trivial.

One of the common objections expressed towards securitization is that it might hurt the firm’s existing creditors. It has been argued in several papers that securitization essentially allows the firm to “judgment-proof” itself by removing assets from the supervision of the bankruptcy court thereby leaving fewer assets for the existing creditors.39 While it should be emphasized that securitization merely replaces one asset with another and does not by itself depletes the assets available for the existing creditors, it has been suggested that

---

38 It should be noted that several prominent states such as Delaware and Texas, have recently adopted state-level ‘safe harbors’ for securitization transactions. Such safe harbors will be effective as long as federal regulation will not supersede them. See Kaye Scholer LLP, 2002, “Will New Delaware Law Facilitate Securitization?”

39 Such argument was chiefly used by the opponents to the proposed federal safe harbor. See a letter dated January 23, 2002, sent by 35 law professors to the Congress committees which contemplated the revisions to the bankruptcy code. See also LoPucki (1996) and Lupica (1998) (these are different authors!)
securitization might be the most efficient tool to transfer assets between claimholders. A firm might securitize some of its assets and distribute the cash proceeds to its shareholders (or invest in negative-NPV projects) at the expense of unsuspecting creditors.

In our model, rational creditors anticipate these effects when their claims are initially priced. If securitization might adversely affect unsecured debt, creditors would demand a higher compensation for their investment such that the lower financing costs of securitization would be completely offset by the higher financing costs of the unsecured debt. While this classic Modigliani and Miller (1958) logic helps achieve an understanding about why securitization is not purely expropriation, it leaves open the question of whether this new financing tool can potentially affect firm value. In our model, securitization can create value because we assume contracts are incomplete in two ways. First, borrowers and lenders cannot write a complete contract that perfectly identifies the states in which a firm is optimally liquidated/continued ex-ante, and contracts are costly to renegotiate in bankruptcy. Second, while bankruptcy law can assist in the renegotiation process (in our model, by preventing secured creditors from holding up the firm and adjusting their claims to the liquidation value of the assets), the code has an inherent bias toward continuation (in allowing for secured creditors to be diluted by DIP lenders). When it is efficient to do so, securitization can create value by “contracting around bankruptcy” when maximal protection of lenders is warranted to prevent inefficient continuation. It is worth noting that this efficiency gain may actually benefit unsecured creditors ex-post, since they are less likely to be diluted by a DIP lender in bankruptcy.

Securitization can therefore be viewed as another form of private contracting innovation market participants use to minimize the costs imposed by a formal, court-supervised, bankruptcy procedure. While such procedure is believed to be necessary to deal with market inefficiencies precluding efficient recontracting of distressed firms, it introduces various costs borne by market participants. Similar to the way prepackaged bankruptcy filings and out-of-court restructuring are used to minimize the costs imposed by Chapter 11, securitization emerges as another private contracting innovation aimed to enhance the efficiency of financial

---

40This argument is of course not unique to securitization; Schwartz (1981) makes a similar argument with respect to secured debt.
distress resolution mechanism when Chapter 11 is not the ideal avenue to pursue.

7 Conclusion

Absent an explicit description of the rights different types of contracts are afforded under bankruptcy law, it is difficult to distinguish between various “debt-like” instruments the firm may use in its capital structure, all of which have priority over equity and acquire additional control rights in the event of default. In this paper, we focus primarily on a recent financial innovation known as asset-backed securities, and compare it to the space of previously-existing financial contracts based on their treatment in bankruptcy. While our model is not intended to supplant existing theories of capital structure, we believe it complements existing theories by considering a richer body of contracts that is difficult to distinguish without an understanding of bankruptcy law and the incentives it creates. Our empirical analysis surrounding the LTV case demonstrate that the bankruptcy treatment of ABS is indeed of first-order importance in the pricing of these contracts: the significant change in ABS spreads following the LTV bankruptcy confirm that bankruptcy remoteness provides creditor protection that is not available with secured debt, and this protection is valued by lenders.

Based on the contractual features of several “bankruptcy-relevant” contracts (ABS, unsecured and secured debt, and leases), our model explicitly accounts for the differential control rights and cash flow rights various classes of lenders receive at bankruptcy. These capital structure choices matter because they affect the eventual use of the assets when a firm goes bankrupt. We model the inefficiencies commonly associated with the bankruptcy process, namely that inefficient liquidations and inefficient continuations may occur; the optimal capital structure will be chosen in equilibrium to minimize the expected efficiency losses from these outcomes.

Two relevant features of Chapter 11, senior DIP financing and the time-value dilution of secured creditors, lead to an inherent bias toward continuation when unsecured and secured debt are the only instruments available and renegotiation is imperfect outside of bankruptcy. Securitization steps in to fill this void. Since securitization involves a “true sale” of the
underlying assets, thus isolating them from the bankruptcy estate, ABS investors can achieve a level of seniority that is not guaranteed for secured or unsecured creditors in Chapter 11. This, in turn, helps alleviate the inefficient continuation problem. The value provided by ABS, however, depends heavily on the nature of assets being securitized. When the backing assets are replaceable, our model predicts that ABS is the most efficient financial instrument. When the securitized assets are necessary for reorganization, however, and the firm cannot easily replace them by resorting to outside markets, securitization can lead to inefficient holdups, and existing instruments such as secured debt and leases are likely to be more efficient.

While we focus the discussion and the model on U.S. bankruptcy law, our model may also be of particular relevance for explaining cross-country patterns in securitization given the obvious interactions between security design and bankruptcy codes. As been argued in previous literature, countries differ in their bankruptcy regimes and in particular in the extent inefficient continuations are likely to occur. For instance, Acharya et al. (2004) argues that since the U.S. has debtor-friendly bankruptcy regime and the U.K. has a creditor-friendly regime, the former is more likely to be characterized with inefficient continuations whereas the latter with inefficient liquidations. Since securitization can minimize continuations in bankruptcy it may be especially valuable for firms operating in bankruptcy regimes subject to excess continuations. Extension of our model to incorporate the differences in bankruptcy regimes across countries seems a promising future research avenue.

A Prospectus of PSNH Holdings

Excerpt from prospectus of PSNH Holdings, April 23, 2001:

BANKRUPTCY AND CREDITORS’ RIGHTS ISSUES

BANKRUPTCY OF THE SELLER COULD DELAY OR REDUCE PAYMENTS ON BONDS AND ADVERSELY AFFECT THE ABILITY TO RESELL RRB PROPERTY

If the seller were to become a debtor in a bankruptcy case, and a creditor or bankruptcy trustee of the seller or the seller itself as debtor in possession were to take the position that the RRB property constituted property of the seller’s bankruptcy estate, and a court were to adopt this position, or a court were to order that the assets and liabilities of the issuer be substantively consolidated with those of the seller, then delays or reductions in payments on the bonds could result. For example, a creditor or bankruptcy trustee of the seller or the seller itself as debtor in possession might argue that the sale of the RRB property to the issuer was a loan to the seller from the issuer, secured by a pledge of the RRB property. Regardless of the court’s determination of the proper characterization of the transaction in a seller bankruptcy case, the mere fact of a seller bankruptcy case could have an adverse effect on the resale market for the bonds and the market value of the bonds.

[...]

Some of the risks described in this section have been illustrated in the bankruptcy cases of LTV Steel Company and certain affiliates, or LTV. Upon the debtors’ motion for interim authority to use cash collateral, the bankruptcy judge allowed the debtors to use receivables (and the related cash proceeds) that had been transferred to LTV’s special purpose finance subsidiary prior to the commencement of the bankruptcy case and pledged by the subsidiary to a third party. As adequate protection for the transferred receivables, the court granted the pledgee a first priority unsecured claim against LTV and a security interest in receivables generated after commencement of the case. In a preliminary ruling denying the pledgee relief from the order, the court observed that the ultimate issue of whether LTV actually sold the receivables to the special purpose finance subsidiary was a fact-intensive issue that could not be resolved without extensive discovery and an evidentiary hearing. The dispute was then settled in conjunction with the approval of senior secured financing that would retire the debt securities issued by the special purpose finance subsidiary.
B Proofs of Propositions and Lemmas

**Proposition 1** When the firm has no necessary assets, it is optimal to securitize all assets-in-place (i.e. securitized assets equal $L_r$), and bankruptcy outcomes are always ex-post efficient.

**Proof.** When $L_r$ is sold to the SPV, the participation condition for the DIP investor is $p_2X^h_2 + (1-p_2)X^l_2 \geq K$. Since this is identical to the efficiency condition when $L_n = 0$, continuation will occur if and only if it is efficient. ■

**Proposition 2** If the firm securitizes necessary assets, there exist $p_2 \in [p^l_2; p^b_2]$ such that $p_2X^h_2 + (1-p_2)X^l_2 - K - L^h_n > 0$ and $p_2X^h_2 + (1-p_2)X^l_2 - K - M^{j*} < 0$; the firm liquidates despite continuation being efficient.

**Proof.** The continuation condition is given by

\[ p_2X^h_2 + (1-p_2)X^l_2 - K - L^j_n \geq 0 \]

Given our assumption that $p_2X^h_2 + (1-p_2)X^l_2 - K - L^j_n > 0$, it is evident from inspection of $M^{j*}$ that it can be rewritten as

\[ M^{j*} = L^j_n + \varepsilon \quad \text{where} \quad \varepsilon > 0. \]

Thus the continuation condition can be rewritten as

\[ p_2X^h_2 + (1-p_2)X^l_2 - K - L^j_n - \varepsilon \geq 0 \]

and the efficiency condition is given by

\[ p_2X^h_2 + (1-p_2)X^l_2 - K - L^j_n \geq 0 \]

Thus, liquidation will occur despite continuation being efficient whenever $p_2X^h_2 + (1-p_2)X^l_2 - K - L^j_n - \varepsilon > 0$, or equivalently, $p_2 \in \left( \frac{K+L^l_n - X^l_2}{X^l_2 - X^l_2}, \frac{K+L^l_n - X^l_2 + \varepsilon}{X^l_2 - X^l_2} \right)$ which is non-empty since $\varepsilon > 0$, and $p^b_2 > \frac{K+L^l_n - X^l_2}{X^l_2 - X^l_2}$. ■

**Lemma 3** The optimal lease policy sets the lease payment on the necessary assets, $F^L_n$, equal to the expected liquidation value $E(L_n)$. The lease payment on the replaceable assets, $F^L_r$, is set such that the lease is always rejected; i.e. the optimal $F^L_r$ is any value such that $F^L_r \geq L^h_r$.

**Proof.** Start by solving the efficiency loss from using leases to find the optimal $F^L_n$. A simplified representation of the efficiency loss is given by the expression below (this assumes that $E(L^h_n - F^L_n) < F^L_n - L^h_n$, which will be true in equilibrium):
\[
\begin{align*}
(1 - \gamma) (1 - \lambda) & \int \frac{K + L^h_n - X^h_2}{X^h_2 - X^l_2} \{p_2 X^h_2 + (1 - p_2) X^l_2 - K - L^l_n\} f(p_2) dp_2 + \\
& \frac{K + L^h_n - X^l_2}{X^h_2 - X^l_2}
\end{align*}
\]

We choose \( F^{L*}_n \), \( F^L_r \) to minimize the above expression. We solve first for \( F^L_n \) given \( F^L_r \).

Applying the Leibniz rule, the first-order condition reduces to:

\[
\begin{align*}
\frac{(1-\gamma)(1-\lambda)}{X^h_2 - X^l_2} [F^L_n - L^l_n] & + \frac{(1-\gamma)\lambda}{X^h_2 - X^l_2} [F^L_n - L^h_n] \\
& + \frac{\gamma(1-\lambda)}{X^h_2 - X^l_2} [F^L_n - (L^h_n - F^L_r - L^l_n)] \\
& + \frac{\gamma\lambda}{X^h_2 - X^l_2} [F^L_n - (L^h_n - F^L_r) - L^h_n] = 0
\end{align*}
\]

solving that we obtain

\[
F^L_n - E(L_n) - \gamma(L^h_n - F^L_r) = 0
\]

And the lease contract for the necessary assets is

\[
F^{L*}_n = E(L_n) + \gamma(L^h_n - F^L_r)
\]

Now solve for optimal \( F^L_r \) given \( F^{L*}_n \):

the first-order condition is given by:

\[
\begin{align*}
\frac{(1-\gamma)(1-\lambda)}{X^h_2 - X^l_2} [F^{L*}_r - L^l_r] & + \frac{(1-\gamma)\lambda}{X^h_2 - X^l_2} [F^{L*}_r - L^h_r] \\
& + \frac{\gamma(1-\lambda)}{X^h_2 - X^l_2} [F^{L*}_r - (L^h_r - F^L_r - L^l_r)] \\
& + \frac{\gamma\lambda}{X^h_2 - X^l_2} [F^{L*}_r - (L^h_r - F^L_r) - L^h_r] = 0
\end{align*}
\]

The expression reduces to

\[
\gamma(L^h_r - F^L_r) \text{ which is clearly minimized by setting } F^L_r = L^h_r. \text{ Since the lease will never be accepted for } F^L_r > L^h_r, \text{ any lease payment such that } F^L_r \geq L^h_r \text{ is equivalent.}
\]
Proposition 4 For the given parameter values, the following capital structures are optimal:

a) When $L_j = 0, \lambda = 1,$ the optimal capital structure is to securitize all existing assets.

b) As $\delta \to 0,$ the optimal capital structure is to securitize all replaceable assets and issue secured debt backed by the necessary assets, with face value of at least $L_h$.

c) As $\text{Var}(L_n) \to 0,$ the optimal capital structure is to securitize all replaceable assets and lease necessary assets with an option to assume the lease at a price $E(L_n)$.

Proof. Part a) of the proposition follows immediately from Proposition 1.

Part b) The efficiency loss from inefficient investment decisions under this capital structure is given by:

$$
\lambda \int \frac{K + L^n_h}{X^2 - X^1_l} \left\{ L^n_h - (p_2 X^2_h + (1 - p_2)X^1_l - K) \right\} f(p) dp
$$

Integrating and simplifying yields the efficiency loss for secured debt:

$$
\text{Loss(Secured)} = \frac{\delta^2 \text{Var}(L_n)^2}{2(X^2_l - X^1_l)(p^2_l - p^2_r)}
$$

Integrating and simplifying (8), using the optimal leasing policy from the proof of Lemma 3 above gives

$$
\text{Loss(lease)} = \lambda(1 - \lambda) \left[ \frac{(L^n_h - L^n_r)^2}{2(p^2_l - p^2_r)(X^2_l - X^1_l)} \right] = \frac{1}{2(X^2_l - X^1_l)(p^2_l - p^2_r)} \text{Var}(L_n)
$$

To prove part (b) of the proposition, note first that the efficiency of loss goes to zero as $\delta \to 0$. If $\text{Var}(L_n)$ is bounded away from zero, leasing or securitizing the necessary assets will necessarily lead to an efficiency loss strictly greater than zero. To see this, suppose first that the necessary assets are leased with an exercise price of $F_n L^n_h$. Then the efficiency loss will approach zero if and only if the replaceable assets are financed with a state-contingent lease with exercise price arbitrarily close to $L^n_r - (F^n_L - L^n_h)$ for each possible realization of the liquidation values. By assumption, this is not feasible since the liquidation values are non-contractible. Similarly, if the firm securitizes the necessary assets, a state-contingent lease on the replaceable assets with exercise price $L^n_r - (M^* - L^n_h)$ would be required which is similarly not feasible.

Given that the necessary assets are financed with secured debt, the optimal (infeasible) contract on the replaceable assets is one that requires the firm to buy the replaceable assets at a price above its liquidation value, $L^n_r + (1 - \delta)L^n_h$. This will never occur in equilibrium since the firm can always borrow in a competitive capital market. Given this, the firm
can do no better than securitizing the replaceable assets, which forces it to pay the highest feasible price \( L^i \).

To prove part (c), note from the expression \( \text{Loss(lease)} \) above that the efficiency loss goes to zero as \( \text{Var}(L_n) \rightarrow 0 \). Using similar arguments as in part (b), it is straightforward to verify that the necessary assets are optimally financed with leases if \( \delta \) is bounded away from zero. Given that this is true, Lemma 3 shows that the optimal treatment of the replaceable assets is to set the exercise price at any level greater than or equal to \( L^h \). This is equivalent to securitization. It remains only to show that the replaceable assets should not be financed with secured debt. Similar to the argument in part (b), conditional on financing the replaceable assets with secured debt, efficiency loss would approach zero if and only if the lease on the necessary assets were state-contingent with a exercise price equal to \( E(L_n) + (1 - \delta)L^i \). ■
Figure 1: Model Time-line

$T = 0$
- Wealthless owner-manger seeks $I_0$ to finance a project using one (or more) of the following instruments:
  - Unsecured debt
  - Secured debt
  - Lease
  - ABS

$T = 1$
- Repayment to investors is due.
- The project yields $X_1^h$ or $0$ with prob. $p_1$ and $1-p_1$, respectively.
- $X_1^h$: Debt is paid off. Game ends.
- $0$: Firm defaults. Bankruptcy protection.
  - $SK$ and any necessary assets are required for continuation.
  - Continuation occurs if DIP financing is obtained to meet the required investment for continuation. Liquidation otherwise.
  - Liquidation value $L$ is composed of two components: replaceable assets ($L_r$) and necessary assets ($L_n$)

$T = 2$
- Conditional on continuation, the payoff is $X_2^h$ or $X_2^l$ with prob. $p_2$ and $1-p_2$, respectively.
- DIP lender and other creditors are paid based on seniority under bankruptcy law.
Table I: The table reports the number of publicly issued securitization transactions executed by financial and non-financial firms in each year for the period 1990-2002. Financial Securitizers are those firms with first-digit SIC code equal to 6 and Non-financial Securitizers are all other firms. Mortgage-backed securities (MBS) transactions are excluded. To be included in this table, a securitization transaction must have been rated by at least one major rating agency, was under the control of a trustee and collateralized by assets of some kind. For a full description of the dataset, as well as additional selection criteria imposed, see Gaon (2004).

Table III: Number of securitizers and extent of securitization by industry: the table reports the number of different firms in each industry that executed a securitization transaction at least once during the period 1990-2002. The Annual Securitization columns report the annual mean, median and standard deviation of the securitization volume for firms that securitized during the sample period. The Ratio columns report the mean and standard deviation of the securitization volume to total assets ratio, conditional on securitization taking place in that year. Mortgage-backed securities (MBS) transactions are excluded. To be included in this table, a securitization transaction must have been rated by at least one major rating agency, was under the control of a trustee and collateralized by assets of some kind. For a full description of the dataset, as well as additional selection criteria imposed, see Gaon (2004).

To be included in this table, a securitization transaction must have been rated by at least one major rating agency, was under the control of a trustee and collateralized by assets of some kind. For a full description of the dataset, as well as additional selection criteria imposed, see Gaon (2004).
Table IV: The table reports means of ABS issuance characteristics for depository and non-depository securitizers. Depository securitizers are those originators identified in the issuance prospectuses as not eligible for Chapter 11. The sample period is for the year centered around LTV Steel filing for bankruptcy protection on December 29, 2000. ABS Spread is spread over maturity-matched swap rates.

Table V: The table reports OLS regression results for a difference-in-differences estimation, investigating the effect LTV Steel bankruptcy had on ABS issuance spreads of non-depository securitizers. Depository securitizers are those originators identified in the issuance prospectuses as not eligible for Chapter 11. The sample period spans the year centered around LTV bankruptcy filing on December 29, 2000. The dependent variable is ABS issuance spreads over maturity-matched swap rates, in percentage. Post-LTV is a dummy variable equal to 1 if the issuance occurred after the LTV bankruptcy. Non-depository is a dummy variable equal to 1 if the securitizer/originator is a non-depository firm. Post-LTV*Non-depository is a dummy created by interacting the variables Post-LTV and Non-depository. Issuance size and Average Life relate to a particular ABS issuance. Standard errors are adjusted for clustering effects at the issuer level.
