What Is Wrong With Representative Agent Equilibrium Models?

Luca Pezzo, Washington University in St. Louis *

January 15, 2017

Abstract

Representative Agent Equilibrium Models (RAEMs) are standard, still very popular, simplifying yet powerful, theoretical frameworks. They match by simulation a growing number of empirical moments but their ability to fit actual data is still quite poor. This study provides a formal setup to analyze what is systematically wrong with these models and how to potentially ameliorate them. Unsurprisingly RAEMs do not work during bad times, characterized by very high levels of market frictions, medium-high information asymmetry, medium-low market demand where aggregate expectations are not rational. Perhaps less obviously and more generally, the probability of RAEMs failures is found counter-cyclical and always quite high, with market frictions being more problematic during recessions and information asymmetries during normal times. The main contribution of this paper is to give a novel, unified and constructive explanation for this findings: the tension of RAEMs in matching the unconditional risk premium makes them over-estimating the risk premium in bad times (and potentially under-estimating it in normal times). This is because in bad times investors are over-optimistic and require a too low compensation for bearing the market risk while in normal times they are over-pessimistic. Equilibrium models featuring informational ambiguity can accommodate this new facts.

*Olin Business School, Washington University in St. Louis, Email: lpezzo@wustl.edu. I am thankful to my advisor P.H. Dybvig, T.A. Maurer, F. Coirelli, O. Kadan, M. Ringgenberg, G. Zhou, A. Manela and my fellow PhD students for helpful comments and discussions. All remaining errors are my own.
1 Introduction

Rational Representative Agent Equilibrium Models (RAEMs) are standard, still very popular, simplifying yet powerful, theoretical frameworks in the literature. Nonetheless, despite their ability to match by simulation an increasing number of unconditional empirical moments, their performances on actual data remain rather poor\(^1\) (causing a large fraction of academics to be concerned), why?

This paper provides a formal setup to analyze what is systematically wrong about these models and when, suggesting how to potentially ameliorate their performances.

RAEMs in the literature\(^2\) feature frictionless, arbitrage-free, exchange economies populated by a single representative agent who, conditional on the (exogenous) endowment process, holds the market in equilibrium and forms rational expectations. Unsurprisingly this models do not work during economic recessions and periods of financial turmoil (approximately 25% of the sample).

The study finds these bad periods to be best characterized by very high levels of market frictions (above the 75-th percentile), medium-high information asymmetry (above the median), medium-low market demand (below the median) and irrationally downward-biased aggregate expectations.

Perhaps less obviously and more generally, the probability of RAEMs failures is found counter-cyclical and always quite high, with market frictions being more problematic during recessions and information asymmetries during normal times.

The main contribution is to give a novel, unified and constructive explanation of this phenomenon: the tension of RAEMs in matching the unconditional risk premium makes them over-estimating the risk premium in bad times (and potentially under-estimating it in normal times). This is because in bad times investors are over-optimistic and require a too low compensation for bearing the market risk with respect to the RAEMs’ benchmark while in normal times they are over-pessimistic (and accordingly might require a too high compensation).

---

\(^1\)In particular, either unreasonable parameter values are required (e.g. the Mehra-Prescott (1985) equity premium puzzle) or by using enough instruments one can always reject the given model (e.g. through the GMM J-test, see for example Hansen-Singleton 1982, Epstein-Zin 1991 and Savov 2011).

These conclusions are reached via a static analysis, centered around a joint model-free test for the RAEMs in the literature able to generate an objective rule to identify subsamples within which the RAEMs are rejected, and extended through a dynamic analysis constructing the probability of RAEMs’ failure at any given point in time. Underlying both analysis there is a novel restriction (Martin, 2016), linking the market premium over the next investment period to observables in the investors’ information set (mostly option data), and an econometric model to forecast the market excess return function of a set of key drivers that proxies for dimensions that go against the main RAEMs assumptions: namely, market frictions, asymmetric information, arbitrage opportunities and the impact of money and the foreign markets. Under the RAEMs’ framework the novel restriction generates a real time lower bound on the market risk premium, while the econometric model generates the objective rule to select the subsamples that are then assessed in the joint model-free test. The test assesses if, on average in the selected subsamples, the ex-post realized excess market return is greater than the ex-ante lower bound implied by the RAEMs and jointly rejects the models if this is not the case. Over the last 25 years in the U.S. financial markets (the sample for which option data is available) the econometric model selects subsamples containing the major economic and financial recessions jointly rejecting the RAEMs, certifying at the 95% level that the risk premium in such bad times is below its RAEMs implied lower bound. Regressing the drivers on the rejection periods documents the predominance of market frictions and asymmetric information over the other relevant dimensions against the RAEMs. A test for rational expectations, comparing the periods of rejections (bad times) with the rest of the sample (normal times), is then constructed systematically detecting over-optimism in bad times (too low required returns vis-a-vis the rational benchmark) and over-pessimism in normal times (too high required returns vis-a-vis the rational benchmark).

Important extensions to these results are achieved by a dynamic analysis where the probability of RAEMs’ failures, constructed via the econometric model as the likelihood that the excess market return at any point in time is below the time t RAEMs’ lower bound, is analyzed. In particular, I am able to (i) disentangle the relative time-varying fragility of the absence of market frictions
and symmetric information assumptions, (ii) extend the documented insight that RAEMs’ performances are problematic during recessions to periods where the GDP growth rate is negative and (iii) further support the claim that rejecting RAMEs in the data is fairly easy. The failure probabilities are right-skewed, counter-cyclical and always quite high: they never go below 33.18% and have a mean of 46.82%. While the counter-cyclicality and the characteristics of the unconditional distribution of the failure likelihoods speak to (ii) and (iii) respectively, isolating the conditional impact of market frictions and asymmetric information on the probability to jointly reject the RAEMs leads to the conclusion that during bad times the most worrisome issue for RAEMs is the presence of substantial market frictions (in line with the static analysis) while in normal times is mostly the presence of asymmetric information.

Another contribution is to find a theoretical framework able to accommodate the new findings: equilibrium models featuring informational ambiguity are a promising venue. Abandoning the price taking assumption and the representative agent construct, thus thinking more in terms of institutional investors than the representative household, Aliyev and He (2016a) have a setup, represented in Figure 1

[ Figure 1 goes about here ]

in which the equilibrium market bid-ask spread surface is increasing in the level of aversion toward ambiguity/pessimism, i.e. decreasing in $\alpha$, as well as in the level of ambiguity/uncertainty, increasing in $\delta$, resulting in bid-ask spread premium/discount for higher/lower aversion to ambiguity and ambiguity itself as opposed to a classical fully rational setup, the horizontal plane. If we let the investors’ attitude toward ambiguity (pessimism vs. optimism) depend on the state of the economy (bad times vs. normal times) then in bad times, characterized by medium-high uncertainty (ambiguity), given investors are optimistic, high $\alpha$, the model can generate a bid-ask spread (which can still be high in absolute term) lower than the one of a classical rational framework (consistent with a risk premium lower than the one associated to full rationality). While in normal times, when the level of ambiguity is low and investors are pessimistic, low $\alpha$, the model can deliver a bid-ask spread (which can be low in absolute terms) higher than the one from a fully
rational framework (in line with a higher risk premium). If we want to stick to the representative agent price taking framework then it seems likely that modifying Aliyev and He (2016b) to include transaction costs one can show that an optimistic attitude towards ambiguity leads to a discount in the risk premium relative to the (classical) rational framework while the opposite happens with a pessimistic attitude.

This paper is not the first to document empirical inconsistencies with existing equilibrium models: the list is long and features Hansen-Singleton (1982)’s or Gallant-Tauchen (1989)’s type of model-specific GMM tests, incompatibility of rational expectations and equilibrium models (e.g. Greenwood-Schleifer (2014) and Amromin-Sharpe (2014)) and simulation-based critiques which show how some relevant data features cannot be replicated even in the idealized models’ frameworks (e.g. Martin (2016) and Moreira-Muir (2016)). Differently from the GMM literature, the present paper jointly analyzes an entire class of models. Unlike other studies reporting violations of the rational expectations in the RAEMs context the proposed rational expectations test is conditional and detect the directions of the biases. Finally, with respect to simulation based critiques the current analysis employs actual data.

The rest of the paper is structured as follows: Section 2 sets the framework of the study explaining the logic behind the model free test and detailing the rest of the empirical design, Section 3 describes the data and motivates the choice of the drivers, Section 4 shows and describes the results from the static and the dynamic analysis, Section 5 contains some robustness checks and Section 6 concludes. All the proofs, derivations and extra-analysis are in the Appendix (Section 7).

2 Framework

2.1 The logic behind the joint model free test

In a recent paper, Martin (2016) proposes a new asset pricing restriction linking the conditional risk premium on the market to observables in the marginal investor’s information set under weak assumptions. I exploit this relation to provide a model free test for the pricing equation in the
where $M$ is the representative agent equilibrium inter-temporal marginal rate of substitution, $R^i$ is the gross return on asset $i$ and $\mathbb{E}\left[\cdot\right]$ is the expectation operator. Each model differs in terms of dynamics and functional forms attached to $M$ and $R^i$, assumes rational expectations, so that investors’ beliefs are in line with the model’ predictions, and mainly focuses on the market return $R^{mkt}$.

By the Fundamental Theorem of Asset Pricing (FTAP), the existence of the pricing equation (1) such that $M > 0$ and an equivalent risk-neutral measure $Q$ such that $R_f = \mathbb{E}^Q[R^i]$, where $R_f$ is the risk-free return, is guaranteed by the Law of One Price, under the assumption of no-arbitrage, the absence of market frictions and by modeling uncertainty through the existence of a potentially very large but finite set $\Omega$ of states of the worlds. It is then straightforward, in the spirit of Martin (2016), to derive the following proposition

**Proposition 1.** In an arbitrage free market where there exists a strictly positive stochastic discount factor, $M$, satisfying the pricing equation and the Negative Covariance Condition (NCC)

\[
\text{Cov}_t(M_{t+1} \times R^{mkt}_{t+1}, R^{mkt}_{t+1}) \leq 0
\]

it is possible to construct a real time conditional lower bound, $LB_t \equiv \frac{\text{Var}^Q(R^{mkt}_{t+1})}{R_{t,f}}$, on the market risk premium $\mathbb{E}_t[R^{mkt}_{t+1} - R_{t,f}]$ by

\[
LB_t = 2 \left( \frac{DY_t}{S_t} \right)^2 \left( \int_{\hat{F}_t} \hat{p}t_t(k)dk + \int_{\hat{F}_t} \hat{c}all_t(k) \right) \geq 0
\]

by setting $DY_t = 1$ the original Martin (2016) measure is recovered.\(^4\)

---

\(^4\)In the Robustness section I show how the two measures are empirically identical.
The quantities with hats are *ex-dividend*, $DY_t$ is the gross dividend yield on the market portfolio with respect to the period $[t, t+1]$ assumed known at $t$, $\hat{S}_t$ is the closing market level at time $t$, $\hat{F}_t$ is the forward contract on the market with tenor $1 = (t+1) - t$ and finally $\hat{\text{put}}_t(k)$ and $\hat{\text{call}}_t(k)$ are European options on the market with unity tenor and strike $k$. By the Put-Call parity the forward contract $\hat{F}_t \equiv \hat{F}_t(k^*)$ is the unique point $(k^*, \hat{F}_t(k^*))$ at which the call and put functions intersect so that $LB_t$ is just a function of $DY_t, \hat{S}_t, \{\hat{\text{put}}_t(k_i), \hat{\text{call}}_t(k_i)\}_{k_i \in \mathcal{K}_t}$ where $\mathcal{K}_t$ is the set of observable strikes with unit tenor at time $t$.

As the next proposition points out, applying the logic of contraposition to Proposition 1 delivers a test for the pricing equation.

**Proposition 2.** Given a violation of the lower bound measure (3) if $M > 0$ and the Negative Covariance Condition in (2) holds the pricing equation is rejected.

Because $M > 0$ and the Negative Covariance Condition in (2) holds for the RAEMs class, following Proposition 2 a test for violations of the lower bound measure (3) is a joint model-free test for the RAEMs. At this point, the only missing element for the formulation of such a test is an operational definition of lower bound violations which is given next:

**Definition 1.** Given a time series for the lower bound on the market premium, $\{LB_t\}_t$, at horizon $1 = (t+1) - t$, computed through (3), and the associated time series for the excess (realized) market return, $\{R_{t+1} - R_{t,f}\}_t$, a lower bound violation is a subsample over which the mean of the excess market return is below that of the lower bound series.

---

5 This assumption is empirically without loss of generality given that it’s impact in the data, as shown in the Robustness section, is absent.

6 Adjusted for dividends, i.e. $\hat{\text{call}}_t(k) = \hat{\text{put}}_t(k) + \hat{S}_t - PV(D_{t+1}) - \frac{k}{R_{t,f}}$.

8 Lagged one period back so to match the forward looking expectations contained in $LB_t$. 

---
2.2 Empirical Design

Armed with the model-free logic this section details how to design a framework to analyze the RAEMs rejections in both a static and a dynamic fashion: statically through the design of a formal test and dynamically through the derivation of a conditional probability to reject the RAEMs based on the information available up to time \( t \) and the realization \( \pi_{t+1} \).

The starting point of both analysis is an econometric model to forecast the excess market return \( \pi_{t+1} \equiv R_{t+1}^{mkt} - R_{t,f} \)

\[
\pi_{t+1} = f_t(D) + \epsilon_{t+1}
\]  

as a function of a set of key drivers \( D \). The flexible modeling choice of the present study is a polynomial of degree 2 (a full quadratic specification) able to capture the linear as well as the non-linear impact of the set of key drivers \( D \) with a vector of parameters \( \theta_t \) iteratively re-estimated at each time \( t \) in the main sample to pick up the time-varying impact of the drivers.

2.2.1 The RAEMs joint model-free test

Define \( y_{t+1} \equiv \pi_{t+1} - LB_t \) and assume \( y_{t+1} \) to be independent over time. The independence assumption states that once we subtract the lower bound \( LB_t \), computed through (3), from the excess market return process, \( \pi_{t+1} \), we are left with noise. Note that we are not restricting such noise to be identically distributed. Given any process \( \pi_{t+1} \), the independence assumption can be justified either by thinking that the lower bound (3) is a good measure for the risk premium, in which case subtracting a good proxy for the conditional mean of \( \pi_{t+1} \) from \( \pi_{t+1} \) just leaves a random disturbance, or on the contrary by viewing \( LB_t \) as a bad proxy containing enough noise to offset any predictable pattern in \( \pi_{t+1} \).

We can now formally state the RAEMs joint model-free test

**Definition 2.** A joint model free test for the class of representative agent equilibrium models (RAEMs) is a one-sided t-test

\[
H_0 : \mathbb{E}[y_{t+1}I_t^{v} (\hat{\pi}_{t+1}, LB_t)] = 0 \text{ vs. } H_1 : \mathbb{E}[y_{t+1}I_t^{v} (\hat{\pi}_{t+1}, LB_t)] < 0
\]  

(5)
with the nonnegative time $t$ function $I^\nu_t(\hat{\pi}_{t+1}, L_{B_t}) \equiv 1_{[\hat{\pi}_{t+1} < L_{B_t}]}$ capturing joint RAEMs violations in case of rejection at the $1 - \alpha$ confidence level, $\hat{\pi}_{t+1}$ representing the time $t$ forecast of $\pi_{t+1}$ according to model (4) and $y_{t+1} \equiv \pi_{t+1} - L_{B_t}$ being independent over time.

Note that, according to Definition 1, the lower bound violations can be written as $\mathbb{E}[y_{t+1}|\mathcal{F}_t] < 0$ for some filtration $\mathcal{F}_t$ and $\mathbb{E}[y_{t+1}|\mathcal{F}_t] < 0$ if and only if $\mathbb{E}[y_{t+1}I_t] < 0$ for any nonnegative function $I_t$. Definition 2 sets $I_t \equiv I^\nu_t(\hat{\pi}_{t+1}, L_{B_t})$. Also, the i.d. assumption on the process $y_{t+1}$ guarantees that $y_{t+1}$ and $I^\nu_t(\hat{\pi}_{t+1}, L_{B_t})$, given information up to time $t$, are independent so that the test does not suffer from any kind of sample selection bias.

### 2.2.2 The conditional probability to reject the RAEMs

The dynamic part of the analysis tackle the issue of when the RAEMs are more problematic rather then why. Remember that, by the logic of Proposition 2, in the RAEMs class, whenever the risk-premium $E_t[\pi_{t+1}]$ is below its lower bound $L_{B_t}$ we have a violation. Thus a way to capture, at any given point in time $t$, the probability of having a lower bound violation and hence a RAEMs rejection, is thorough the following object $P_t(\pi_{t+1} < L_{B_t})$.

In particular, using model (4) I construct the time-series of such conditional probabilities and further produce the conditional contributions due to specific subset of drivers $d \subset D$.

Model (4) produces the forecast $\hat{\pi}_{t+1}$ at each time $t$ which can be viewed as

$$\pi_{t+1} = \hat{\pi}_{t+1} + \varepsilon_{t+1} \quad (6)$$

thus at each time $t$ retrospectively, the researcher has at disposal the time series $\{\hat{\varepsilon}_{t+1}\}_{t=1}^T$ where $\hat{\varepsilon}_{t+1} \equiv \pi_{t+1} - \hat{\pi}_{t+1}$. One can then, according to (6), re-create the conditional distribution of $\pi_{t+1}$ by bootstrapping $^9 \{\hat{\varepsilon}_{t+1}\}_{t=1}^T$ and compute $P_t(\pi_{t+1} < L_{B_t})$ by subtracting $L_{B_t}$, counting the number of times $\{\pi_{t+1}^{(s)} - L_{B_t}\}_{s=1}^{Sim}$ is negative and dividing it by $Sim$, the number of bootstrapping simulations.

Using a similar logic and model (4), the single contribution of subsets of drivers $d \subset D$ on the

---

^9 Or block-bootstrapping to more precisely take into account potential serial correlation.
probability to reject the RAEMs, $P_t(d: \pi_{t+1}(d) < LB_t)$ is also computable, this time only using information up to time $t$. As a matter of facts, model (4) gives us $\pi_{t+1}$ as a function of $D$ and the model parameters given information up to time $t$, $\theta_t$. $P_t(d: \pi_{t+1}(d) < LB_t)$ is computed by looking at the joint empirical frequency of $d$ using the sample $\{1, ..., t\}$ such that at time $t$ for given $\theta_t$ and $d^c = D - d$ fixed at their time $t$ realizations, $\pi_{t+1}(d) < LB_t$.

3 Data

The data used in this study is at the monthly frequency and covers the United States Financial Markets over the period $Feb : 1973 - Dec : 2014$. The sample is split into a training sample $TS = \{1, ..., T_s\}$ and a main sample $MS = \{T_s + 1, ..., T\}$ with $T_s = Dec : 1989$. Model (4) is initially estimated in the training sample, thus $\hat{\pi}_{t+1}$ with $t+1 = T_s + 1$ uses the parameter vector $\theta_t$ calibrated exclusively in $TS$ and for each following $t \in MS$ the parameter vector $\theta_t$ is re-estimated using information up to time $t$ included. The RAEMs analysis is conducted in $MS$ only and the choice of $T_s$ is due to the availability of option data, that is, $T_s + 1$ is the first date for which option quotes are available. The study is conducted from the perspective of an investor taking the investment decision on whether to invest in the market portfolio or the risk free asset over the next month given information up to the evening of the first business day of the month. Consistently, we define the investment horizon of one month as the period between two consecutive months’ first business day evenings. The data is divided into two categories: (i) the Main Variables, the key variable of interest, namely the market return $R_{t+1}^{mkt}$, the risk-free return $R_{t,f}$ and the lower bound $LB_t$ and (ii) the Drivers $D$. Each category is detailed next.

---

10I.e. avoiding the usage of realization $\pi_{t+1}$.

11For all the ambiguous cases in which it is not clear what is the exact timing of an observation recorded at $t$ we lag it back one period to make sure it is in the investor information set at specified time $t$. If anything, this step only makes it harder to find the results of this study.
3.1 Main Variables

The gross total market return is defined as \( R_{t+1} \equiv \frac{\hat{S}_{t+1}}{S_t} DY_t \) where \( \hat{S} \) represents the daily closing level of the Standard & Poor’s 500 (SP500) index and \( DY_t \equiv 1 + \frac{D_{t+1}}{S_{t+1}} \) is the gross dividend yield with \( \{D_t\} \) being the SP500 dividend time series (divided by 12) available on Prof. Shiller website.\(^{12}\) The gross return on a risk-free investment, \( R_{t,f} \), is defined as the gross yield to maturity extracted from the Center for Research in Security Prices (CRSP) continuously compounded yield curve computed over liquid secondary market transactions on U.S. Treasuries.

The time-series of the market premium lower bound, \( \{LB_t\} \), is computed according to equation (3) in the most conservative way by a cubic spline interpolation\(^{13}\) on the Chicago Board Options Exchange (CBOE) SPX options closing bid prices; the data from January 1990 through December 1995 is provided by Optsum data, while data from January 1996 through December 2014 is taken from OptionMetrics. For dates \( t \) in which the data is not sufficient/absent to deliver \( LB_t \) at the exact maturity of 1 month I linearly interpolate between the contemporaneous \( t \) lower bounds with the two closest maturities.

The following table summarizes the main variables

\[ \text{Table 2 goes about here} \]

3.2 Drivers

The set \( D \) of drivers plays an important role in the interpretation of the RAEMs analysis: they represent the conditioning upon which the equilibrium models fail. As such, they are selected with the goal of describing dimensions that go against the RAEMs assumptions. In particular, we know that the first order conditions of such models give the pricing equation (1) under the testable\(^{14}\) assumption of no-arbitrage and the absence of market frictions: thus the first couple of dimensions we want to include should contain proxies for arbitrage opportunities and market frictions. We

\(^{13}\) In the Robustness section I show how very similar results are obtained if we use a linear interpolation instead.

\(^{14}\) As we detailed in Section 2 we also need the Law of One Price and the finiteness of the state space but these are not testable.
also know that the class of RAEMs only deals with closed\textsuperscript{15} exchange economies thus the impact of money and foreign markets is outside the scope of the models: for this reason the next couple of dimensions we want to have are those which contains proxies for the value of money and the impact of foreign markets on the pricing of the domestic assets. A final important dimension is the one concerning the representative agent and its existence, as the proposition below motivates, an essential (and stringent)\textsuperscript{16} assumption in this context is the homogeneity of investors’ beliefs

**Proposition 3.** If the following hold

- The set of intervals the time period $[0,T]$ can be divided into, the set $\Omega = \{\omega_t\}_{t=0}^T$ of states of the world, and the set of investor types $J$ are finite
- Investor type $j$ have homogeneous beliefs and standard\textsuperscript{17} von-Neumann Morgenstern utilities over the consumption process $\{c_{j,t}(\omega_t)\}_{t=0}^T$
- The Law of One Price hold, the financial market is complete, arbitrage-free and features a finite number, $N + 1$, of primitive securities with ex-dividend price processes, $S_t = (S_0,t, ..., S_{N,t})$
- The space of feasible net trades is linear (markets are frictionless)

Then for any aggregate endowment process the resulting exchange economies have Pareto optimal competitive equilibria with prices that equivalently sustain a no-trade economy with a single agent, with Inter-temporal Marginal Rate of Substitution (IMRS)

$$M_{t+1} \equiv \beta \frac{u'_{t+1}(C_{t+1})}{u'_t(C_t)}$$

holding the market in equilibrium and optimally consuming the aggregate endowments $C_t \equiv \sum_{j=1}^J c_{j,t}$.

\textsuperscript{15}Or more generically, the impact of foreign markets is not explicitly modeled.

\textsuperscript{17}Strictly increasing, strictly concave, time-additive and state-independent preferences.
Proof. See Appendix. ■

the proposition shows how under the additional requirements of market completeness, vNM preferences and the testable assumption of homogeneity in beliefs we can construct a no-trade economy with a single agent, the representative agent, superscript 18 holding the market portfolio, in the RAEMs framework.

In light of these reasoning and in the sake of parsimony I select the following drivers:

\[ D = \{F, SII, TAXchg, ILLIQ, MDI, BM, USDg\} \]  

(7)

where:

1. \(F\), as a proxy for investors’ disagreement\(^{19}\), is the Ludvigson et al. (2016) financial uncertainty measure: computed as the cross-sectional average conditional volatility of the 1-month Root Mean Squared Error in predictive regressions over approximately 150 monthly financial time series.

2. \(SII\), as a proxy for investors’ disagreement\(^{20}\), is the Rapach et al. (2016) short interest index: computed as the log of the equal-weighted mean of short interest (as a percentage of share outstanding) across all publicly listed stocks on U.S. exchanges.

3. \(TAXchg\), as a proxy for market frictions, is the annual time series of the rate of change on total taxes paid on capital gains as reported by the U.S. Department of the Treasury.

4. \(ILLIQ\), as a proxy for market frictions, is the negative of the Pastor-Stambaugh (2003)\(^{18}\) financial uncertainty measure.

\(^{18}\)In reality, even if in the modern finance jargon it is called the representative agent, such single agent is an ex-post representative agent in that is mainly a device used to explain ex-post a set of observable prices thought to be in equilibrium. Aggregate consumption in equilibrium is a function of the aggregate wealth and the asset prices, this implies that if prices changes than also the (aggregate) endowment and thus the agent holding the market in equilibrium change. Therefore the ex-post representative agent pins-down just a point, the equilibrium one, in the aggregate demand function. A true ex-ante agent needs to have the extra additional requirement of preferences that are independent from the aggregate endowment and the prices distributions. Unfortunately such agent can only be derived under very restrictive assumptions. (See Lewbel (1989))

\(^{19}\)In the Appendix it is shown that 80% of the variability of \(F\) can be explained using a number of disagreement proxies only, generating an estimate which correlates 0.9038 with the original series.

\(^{20}\)High values of the index indicate that a sizable portion of investors is betting on the market going down by short-selling stocks. Selling large amounts of stocks is only possible if on the other side of the transactions there are buyers, i.e. investors who presumably think, for whatever reason, that holding the market is better.
liquidity index: computed as the (negative of the) aggregate average (over a month) daily response of signed volume to next day return for all individual stocks on the New York Stock Exchange and the American Stock Exchange.\textsuperscript{21}

5. \textit{MDI}, as a proxy for arbitrage opportunities, is the Pasquariello (2014) Market Dislocation Index: computed as a monthly average of hundreds of individual abnormal absolute violations of three textbook arbitrage parities in stocks, foreign exchange and money markets.

6. \textit{BM}, as a proxy for arbitrage opportunities (through miss-pricing), is the book-to-market ratio taken from Goyal database:\textsuperscript{22} book-to-market value ratio for the Dow Jones Industrial Average.

7. \textit{USDg}, as a joint proxy for the value of money and the impact of foreign financial markets\textsuperscript{23}, is the U.S. Dollar appreciation index: computed as the linear return on the Trade Weighted U.S. Dollar Index available from the Saint Louis Federal Reserve\textsuperscript{24}

The next table gives the summary statistics of the selected drivers

[ Table 3 goes about here ]

We conclude this subsection by illustrating, through the correlation matrix below, how the parsimoniously selected drivers, indeed cover a variety of different information sources

[ Table 4 goes about here ]

The average absolute correlation is 0.1119 with the highest linear association of 0.3743 being the one between \textit{F} and \textit{ILLIQ} followed by the 0.3187 between \textit{F} and \textit{MDI}. In the appendix we

\textsuperscript{21}The intuition behind the measure is that if we view liquidity as the ability to trade large quantities without moving the price and think of signed volume as a proxy for the order flow then lower liquidity is reflected in a greater tendency for order flow in a given direction on day \textit{d} to be followed by a price change in the opposite direction on day \textit{d} + 1.

\textsuperscript{22}Available at http://www.hec.unil.ch/agoyal.

\textsuperscript{23}The latter, as reported by Bertaut-Judson (2014) on behalf of the Board of Governors of the Federal Reserve System, is a consequence of the fact that the U.S. runs a deficit in the current account since 1985 and the excess of imports over export has been funded primarily by foreign acquisitions of U.S. securities. See also Walker (2015).

\textsuperscript{24}The index is a weighted (over the volume of bilateral transactions) average of the foreign exchange value of the U.S. dollar against the currencies of a broad group of major U.S. trading partners.
show how, despite a level of correlation of 0.3743, \( F \) and \( ILLIQ \) are fundamentally different in that only the first one can be replicated (almost entirely) by disagreement proxies, while in the Robustness section we document how using a version of \( MDI \) orthogonalized from \( F \) gives very similar results suggesting the difference in the \( F \) and \( MDI \) contents is what is driving the result in the main specification.

4 Results

This section reports the main findings of the paper over the last 25 years in the U.S. financial market and discuss them.

I start providing the specifics of the econometric model to predict the excess market return which is the base for the analysis, then I describe the results from the static analysis centered around the conditional model free joint test for the RAEMs: in this subsection, once the rejection periods are identified, they are thoroughly analyzed and used to implement a test for the rational expectations. Three RAEMs’ fragilities are detected as key: the role of market frictions, that of asymmetric information and the fact that aggregate expectations are not rational. In order to extend some of the conclusions from the static analysis and further justifies the relative ease in empirically rejecting the RAEMs, the next subsection shows the results from the dynamic analysis. The main findings concern the time-varying relative importance of market frictions and asymmetric information as well as the characteristics of the unconditional distribution of the conditional probabilities to reject the RAEMs at any point in time in the main sample.

4.1 The econometric model for the excess market return \( \pi_{t+1} \)

As discussed in Section 2 the econometric model for the risk premium (eq. (4)) is the base for both the static and the dynamic analysis of RAEMs. The chosen specification is

\[
\pi_{t+1} = f_t(D) + e_{t+1} = g_t(D)\theta_t + e_{t+1}
\]
with \( g_t(D) \) being a full second order polynomial of the drivers \( d \in D \), that is, if \( D = \{d^1, d^2\} \) then \( g_t(D) = 1 + d^1_t + d^2_t + d^1_t \times d^2_t \) and \( \theta'_t = [\theta^0_t, \theta^1_t, \theta^2_t]' \). In this paper, being \( D \) defined by 7 drivers, the vector of parameters contains 36 elements. We use 2 competing estimation methods, \( OLS \) and the Lin-Wu-Zhou (2016) Iterated Combination Method, \( ICM \), which is equivalent to a shrinked regression (\( OLS \)) in which the out-of-diagonal elements in the regressors’ matrix are set to zero and the regressors’ coefficients are divided by the number of regressors, and select the one that serve our purpose, one step ahead out-of-sample forecasting, the best, i.e. the \( ICM \) model. The horse-race results are shown in the following figure

[ Figure 2 goes about here ]

The blue solid line plots the actual excess return, \( \pi_{t+1} \), the \( OLS \) forecasts, \( \pi^{OLS}_{t+1} \), are displayed by a red dashed line while the dot-dash green line shows the \( IMC \) forecasts, \( \pi^{IMC}_{t+1} \): the top panel illustrates the in-sample forecasts against the actual data in the training sample \( TS \), while the bottom one the one-step ahead out-of-sample estimates in the main sample \( MS \). The models are compared, both in and out of sample, in terms of their coefficients and \( R^2 \) in the following regression

\[
\pi_{t+1} = \alpha + \beta \pi^{Mod}_{t+1} + u_{t+1} \quad \text{with } Mod \in \{ OLS, IMC \}
\]

a good model should have \( \alpha = 0 \), \( \beta = 1 \) and an high \( R^2 \). The estimates of these parameters are reported in the legends: none of the model is spurious\(^{25}\). \( OLS \), as expected,\(^{26}\) performs better in-sample, while \( IMC \), specifically design to deliver superior out-of-sample performances, does a better job out of sample.

### 4.2 Static analysis

We now use the selected \( IMC \) model to construct the conditional joint model free test for the RAEMs: basically the model is used to construct an objective rule, \( I^v_t \equiv 1_{[\pi_{t+1} > LB_t]} \) with

\(^{25}\)The persistence of the \( \beta's' 95\% \) upper confidence intervals are (well) below 1.

\(^{26}\)Since over-fitting is an issue in this context.
\( \pi_{t+1}^{\text{IMC}} \equiv \pi_{t+1} \), to select the candidate subsample of MS, as a function of the drivers \( D \), over which to run the joint RAEMs violation test (eq. (5)). The results are shown in Table 5

[ Table 5 goes about here ]

as the figure in bold shows, the objective rule \( I^v_t \) have selected a subsample within which, at the 95% confidence level, the RAEMs in the literature, as per Proposition 2, fail. As a matter of facts, the conditional risk premium is below its average lower bound (as implied by the RAEMs) by a solid monthly 1.65%. That is, according to RAEMs’ predictions, the risk premium over this subsample should have been on average at least 0.6%, the same order of magnitude as the conditional risk free rate, both the former and the latter statistically significant at the 99% level. What the data says is that the conditional risk premium is below 0.6% at the 95% level instead. The result is confirmed by the economic, but statistically insignificant values of \( \pi|I^v \) and \( R_{\text{mkt}}|I^v \) of \(-1\)% and \(-0.4\)%.

In the Robustness section we show that the result is driven by the dynamics of the market return rather than those of the lower bound, \( LB_t \), or the risk-free return, \( R_{t}^{f} \).

Remember that, in order for the above test to be correctly specified and not biased, we need \( y_{t+1} \equiv \pi_{t+1} - LB_t \) to be independent. While this assumption cannot be formally tested we can nonetheless gives supporting evidence: Figure 3 below

[ Figure 3 goes about here ]

shows the correlogram of \( y_{t+1} \) together with the 95% confidence bands confirming the absence of any linear form of dependence, while the other statistics of interest concerning the \( y_{t+1} \) process are summarized in the next table

[ Table 6 goes about here ]

the statistics, in line with Martin (2016), document the unconditional tightness of the lower bound measure in that the mean of \( y \), 0.0028, is economically positive not statistically different from 0

\[ \text{17} \]

\footnote{This last two figure alone do not suggest nor imply a negative risk premium, the variability of the estimates is just too much so that one can view them as the results of a pure random draw.}
and confirm the usual estimate for the unconditional risk premium, 0.0061 (0.0732 annualized)\(^2\). So far, through the joint model-free test, we have selected “chunks” of the main sample MS in correspondence to which the time series of \(y_{t+1}\) is such the RAEMs fail: the risk premium conditional on the “chunks” is below the average conditional lower bound. The next figure show how these chunks and the corresponding values of \(y_{t+1}\) look like

[ Figure 4 goes about here ]

the values of \(y_{t+1}\) in correspondence to the rejection periods highlighted by the function \(I^v\) are displayed via a dashed red line, the \(y_{t+1}\) process is illustrated by the blue solid line and the pink shaded area pick up the National Bureau of Economic Research (NBER) economic recessions. Note how the rejection periods contains all the NBER recessions as well as additional times of financial turmoil such as the 1998 Long-Term Capital Management Crises and the Euro sovereign bond crises in the aftermath of the Great Recession.

Our next task is to analyze such rejection periods more in detail: as we just spotted through the previous figure \(I^v\) has selected bad economic and financial periods. Is there something that systematically goes wrong in terms of RAEMs assumptions over these periods? In order to answer this question I run the following regression

\[
I_t^v = \beta_0 + D_t\beta + u_t \tag{8}
\]

and report the result in the next table

[ Table 7 goes about here ]

note how the first three drivers \(F, SII\) and \(ILLIQ\) are key: all their coefficients are significant at the 1% level, their partial \(R^2\) are at least 3 times those of the remaining drivers and, as highlighted by the last column of the table, running regression (8) only using the first three drivers explains 0.4537 of the violation function \(I^v\), which is 90% of the variability explained by using the whole set

\(^2\)As we will further discuss later, the conditional as well as the unconditional properties of \(y\) are consistent with a high unconditional risk premium, targeted by equilibrium models, mostly driven by a high risk premium in periods in which RAEMs are not rejected.
of drivers $D$. As we show in the Appendix, $F$, the index of financial uncertainty, can be thought as a proxy for investor disagreement, the same holds true for $SII$, the index that tracks the aggregate amount of short selling, while, still in the Appendix, we show the tight link between the illiquidity measure $ILLIQ$ and the bid-ask spread on the market portfolio. We therefore conclude that the key drivers explaining the RAEMs rejections are proxies for investors’ disagreement (asymmetric information) and proxies for market frictions (illiquidity and bid-ask spreads). We showed how $F$, $SII$ and $ILLIQ$ are the main responsible for the RAEMs rejections; next we illustrate how the violation sub-sample defined by $I^v$ can indeed be characterized in terms of the main detected drivers. Consider the following model

$$d_t = \alpha_1 I^v_t + \alpha_2 (1 - I^v_t) + w_t, \text{ with } d_t \in \{F_t, SII_t, ILLIQ_t\}$$

(9)

model (9) compares the conditional mean of the dependent variable $d$ in the violation periods with the one computed in the rest of the main sample. Table 8 reports the results of model (9)

Table 8 goes about here.

The key drivers $F$, $SII$ and $ILLIQ$ are substantially different in periods of RAEMs failures, as a matter of facts, the difference in their means in the violations’ periods and non-violation’ periods are statistically significant at the 1%. All drivers have higher values in rejections’ periods, in particular, the disagreement proxies ($F$ and $SII$) are above their unconditional median while illiquidity is above its unconditional 75-th percentile. Thus we conclude that rejections’ periods are characterized by substantial investors disagreement and high illiquidity. A similar analysis conducted in the Appendix also reviles that medium-high bid-ask spreads and medium-low market demand further describe the rejection periods.

We conclude the static analysis with the results concerning the violation of the rational expectations assumption, since this is an important point in the interpretation of the results we dedicate a separate subsection to it.

---

in the same subsection that illustrates the link between $ILLIQ$ and the bid-ask spread and in the next one.
4.2.1 Irrational Expectations

One of the key pillars of the RAEMs is the rational expectations assumption: as briefly mentioned in Section 2.1, this is a consistency requirement on the agents’ expectations so that they are aligned with the models’ predictions. In other words, investors’ expectations have to be correct, at least on average and over time (Muth, 1961). Recently Greenwood-Shleifer (2014) and Amromin-Sharpe (2014) documented how equilibrium-based required returns and investors’ expectations display a counter-intuitive negative correlation casting doubts on the compatibility of rational equilibrium models and actual data. In this subsection I test whether we can detect systematic biases in the investors’ expectations in the presence of RAEMs rejections and in order to do so I run the following regression

\[ z_{t+1} - \mathbb{E}_t[z_{t+1}] = \gamma_1 I_t^v + \gamma_2 (1 - I_t^v) + \eta_{t+1} \]  

(10)

The random variable \( z_{t+1} \) is the quantity over which investors, using information up to time \( t \) included, form expectations \( \mathbb{E}_t[z_{t+1}] \). Following the logic of model (9), I compare the conditional mean of the forecast error, \( z_{t+1} - \mathbb{E}_t[z_{t+1}] \), in the presence of RAEMs rejections, captured by \( \gamma_1 \), and in the rest of the sample, detected by \( \gamma_2 \). Note that specification (10), as specification (9) before, suffers from the errors-in-variable problem in that the regressor \( I_t^v \) is itself an estimate.\(^{30}\) Such bias in linear regressions deflates the real (unobservable) coefficients \( \gamma_1 \) and \( \gamma_2 \) towards zero, so that any significant result we find is robust to this problem.\(^{31}\) The next table reports the result of this analysis

[ Table 9 goes about here ]

I use four different popular financial indicators as random variables over which investors form expectations and three different methods to capture such expectations. In the first five columns \( z_{t+1} \) represents the return of the market in excess of the risk-free rate and the expectations are collected from survey data (Gallup, American Association of Individual Investors, Shiller, Graham

\(^{30}\) We are in fact sure at the 95% that it contains RAEMs violations not at the 100%.

\(^{31}\) This is the reason why I did not mention the issue while describing model (9).
and Harley, and Michigan) validated in Greenwood-Shleifer (2014). $z_{t+1}$ in the sixth column represent inflation, $Infl$ and the expectations are the market implied (and priced) ones from the difference in the yield of 5-year inflation indexed treasury bounds and the yield of 5-year nominal treasury bonds. In the last two columns $z_{t+1}$ captures a key economic indicator, the U.S unemployment rate, $UR$, and a core financial indicator, the spread between the BAA rated corporate bonds and the federal funds rate, $SP$; expectations in this case are computed as forecasts through the specification of an econometric model following the Box-Jenkins (1970) procedure (See Appendix for the details on the specification procedure).

Under the null of rational expectations $\gamma_1 = \gamma_2 = 0$, that is, there is no systematic bias in the time series of forecasted errors $z_{t+1} - \mathbb{E}_t[z_{t+1}]$. In 6 out of 8 cases covering the three different methodologies implemented for inferring the investors' expectations, $\gamma_1 > 0$ with a significance level of 5% for the Gallup market return expectations and the model-based unemployment rate expectations. The exact same pattern repeats for the case of $\gamma_2 < 0$, only this time the Gallup estimate is significant at the 1%. Furthermore, in 4 out of 8 cases covering the survey and model-based expectations, $\gamma_1 \neq \gamma_2$ at the 5% and 1% level. These results suggest a consistently irrationally sizable downward bias in the expectations during periods of RAEMs rejections (bad times) and a consistently irrationally sizable upward bias in the expectations during periods in which we cannot reject RAEMs (normal times). Note a downward bias means that investors are over-optimistic: this is immediate to see in the case $z_{t+1}$ is the unemployment rate and requires bit more thinking for the other traded quantities. Take the leading examples where $z_{t+1}$ is the market risk premium (inflation and the spread follows an analogous logic); if investors despite being in bad times require a lower compensation for the market risk, $\mathbb{E}_t[\pi_{t+1} | t]$, it is because they expect the future conditions not to be as bad, while ex-post it turns out they could have asked for a higher premium, i.e. $\pi_{t+1}$ is systematically higher, an investor forming rational execrations would have asked for an higher premium, meaning the investors under-estimated the risk embedded in

---

$^{32}$Expectations reported by surveys in month $t$ are use at the beginning of month $t+1$ following the convention explained in Section 3. The rationale behind is to think that the most accurate expectations at the beginning of month $t$ are those formed over the previous month. Because the time-series of survey expectations are computed as spreads between the percentage of bullish and bearish investors they are not on the same scale of realized excess returns, thus I standardized both series in order to make them comparable.
the prices, hence they have been over-optimistic. Following the same logic, a consistent upward bias in expectations in normal times implies that investors have been over-pessimistic. Overall we find evidence against the rational expectations, in particular in bad times investors behave over-optimistically while in normal times they are over-pessimistic.

4.3 Dynamic analysis

The second part of the analysis of the RAEMs failures is dynamic: having certified, at 95% confidence, that such models fail and attempted to gather enough evidence as per why we now turn to the study of when it is more probable that this happens.

Figure 5 plots the conditional probability distribution \( \hat{P}_t(\pi_{t+1} < LB_t) \) of rejecting the RAEMs at each point in time in the main sample \( MS \) against the negative of the GDP growth\(^{33} \) and shows its empirical distribution. The probability to reject the RAEMs is right-skewed, well approximated by a lognormal distribution, and always quite high: it has a mean of approximately 47% (median of 41.08%) and never goes below 33.18%. The time-series is counter-cyclical, having a negative correlation with respect to the U.S. GDP growth of 0.4817, and very high during the Great Recession period. Other notable spikes occur in periods of financial distress such as the 1998 long term capital management crises or in the sovereign debt crises in the aftermath of the Great Recession.

Thus, unsurprisingly, models perform worst in periods of high financial distress, however more interestingly, due to the counter-cyclical nature, the pattern generalizes to all periods defined by a negative GDP growth. As a matter of facts, in these periods the average probability to reject the RAEMs is 48.17%, statistically greater than the analog probability, 45.63%, in periods of economic expansions. Also, the fact that the probability to reject is always quite high justifying the documented poor empirical fit.

Next I investigate the contribution of the main drivers \( d \subset D \) on the conditional probability to reject the RAEMs. In the Robustness section I show how the ranking found in the static

\(^{33}\)The pink areas represent the NBER recessions.
analysis is the same and the first three most important drivers are still the disagreement proxies \( F, SII \) and the illiquidity measure \( ILLIQ \) explaining 82.92\% of the variability explained by all drivers. The results are shown in Figure 6: in the upper graph the joint contribution of the disagreement proxies \( F, SII \), which can be viewed as a new structural index, is plotted in the form of a dashed red line, the contribution of the illiquidity index \( ILLIQ \), which can also be regarded as a novel structural proxy, is represented by a dotted green line, while the overall conditional probability of rejecting the RAEMs is still a solid blue line as in Figure 5. Note how the new indexes explain all the most notable spikes in the overall rejection probabilities. The novel structural proxies, even if, as expected\(^{34}\), are highly correlated (with a coefficient of 0.7160), carry nonetheless different information as displayed by the bottom graph. The solid light blue line tracks the difference between the disagreement and the illiquidity series; positive values indicate a higher contribution of structural disagreement while negative values a predominant contribution of structural illiquidity. The emerging pattern is interesting, the RAEMs are impaired over time for different reasons: around NBER recessions the probability that models fail is mostly due to the illiquidity (or market frictions) component, while in normal times is mostly the disagreement (thus the failure of the symmetry-in-information assumption) part that drives the failures’ likelihood.

5 Robustness

Any of the subsection below is independent and can be read on its own.

5.1 Linear versus cubic spline lower bound

In order to compute the lower bound measure at time \( t \), \( LB_t \), according to equation (3) we use the SPX option (Put and Call) bid quotes at horizon 1 month for the different available strikes as at the end of day \( t \) from Optsum and Optionmetrics. In order to compute the integral in (3) we first need to interpolate the functions \( \hat{put}(k) \) and \( \hat{call}(k) \) over a continuum of strikes. Because theoretically we know of the convexity of these functions, in the study so far we have used a

\(^{34}\)By construction they are both intimately linked to the overall rejection probability time-series.
cubic-spline interpolation. Another obvious interpolant option is the linear one; Figure 7 shows
the time-series of lower bounds in the main sample $MS$ computed with the linear as well as the
cubic-spline method

[ Figure 7 goes about here ]

the upper graph plots the two time series while the bottom one shows, in percentage, the abso-
lute difference in terms of the cubic-spline approximation. The two time-series are overall very
similar, the mean absolute difference is 2.4358% with most of the differences in the periods pre-
Optionmetrics (i.e until 1996). All the results in the paper are unaffected by the way we compute
the bounds.

5.2 The impact of dividends on the lower bound measure

Martin (2016) derives a lower bound for the risk premium, $LB_M$, which is an implicit function
of the market dividends. In his formulation dividends are assumed known and part of the SP500
index. Following this assumption all the contracts on the SP500 are to be considered as if written
on the total value of the index rather than the ex-dividend one, an expedient which simplify the
derivations and it is equivalent to the assumption that there are no dividends at all: as a matter
of fact in my derivation $LB \equiv LB_M$ if and only if the gross dividend yield $DY_t$ is equal to 1. I
argue that, more realistically, one should account for the fact that such contracts are written on
the ex-dividend level of the SP500 so that dividends (or divided yields), even if assumed known,
should become an explicit input in the lower bound derivation. Empirically whether they are a
function of the dividends or not and whether dividends are indeed to be considered deterministic
or stochastic turns out to be irrelevant in the current analysis. However, the realization of such
a convenient simplification, would have been otherwise impossible to detect if no such formula,
namely equation (3), for the bound as a function of dividend had been derived. I now make the
argument concrete by showing Table 10 which compares the key moments of the lower bound

---

35 This way the stochastic component of $S$ only comes from the ex-dividend level $\hat{S}$. 

24
empirical distributions under the Martin, $LB_{M}^{m}$, and the current, $LB^{m}$ setup for the linear $m \equiv l$ interpolation as well as the cubic-spline $m \equiv cs$

(Table 10 goes about here)

the four distributions are virtually the same: it is evident how the empirical role of deterministic dividends be negligible. Nonetheless, the conclusion in the current framework is even more general:

if dividends were stochastic and the correlation between the gross dividend yield and the ex-dividend market return was zero, $\rho \equiv \text{corr}(DY_t, \hat{R}_{t+1}^{mkt}) = 0$, then $\text{Var}^{Q}(R_{t+1}^{mkt}) \approx \text{Var}^{Q}(\hat{R}_{t+1}^{mkt})$ so $LB_{M}^{m}$ would still be a good overall measure. The overall in-sample correlation is $\hat{\rho} = -0.0515$ with a p-value of 0.2334. I thus conclude that the impact of dividends is empirically irrelevant.

5.3 Joint RAEMs’ rejections driven by the market return dynamics

In the Results section I show that the joint model-free test for the RAEMs rejects the models at the 95% confidence. In this subsection I re-run the same test except that I fix the risk free return, $R_{t}^{f}$, and the lower bound, $LB_{t}$ to their unconditional mean; that is, I kill their dynamic so that any result now directly comes from the market return dynamics. The results are shown in the next table

(Table 11 goes about here)

again, as the bold figure illustrates, we jointly reject the RAEMs at the 5% level confirming that the outcomes of the joint test in the Results section are driven by the dynamics of the market return rather than those of the risk free return or the lower bound.

5.4 Explaining RAEMs’ failures via the rejection probabilities

In section 4.1.1 (Table 6) we show that the key drivers in the rejection of the RAEMs are the disagreement proxies $F$ and $SII$ as well as the (negative) of the Pastor-Stambaugh (2003) illiquidity index $ILLIQ$, a similar conclusion can be reached if instead of explaining the joint
rejections, captured by the indicator function \( I_v(\hat{\pi}_{t+1}, LB_t) \equiv 1_{[\hat{\pi}_{t+1} < LB_t]} \), we regress the drivers \( D \) on the conditional probabilities to reject the RAEMs according to the model

\[
P_t(\pi_{t+1} < LB_t) = \beta_0 + D_t\beta + u_t
\]

(11)

the results are reported in the following table

[ Table 12 goes about here ]

note that, according to the partial \( R^2 \), \( F, SII \) and \( ILLIQ \) are still the first most important variables capturing \( 82.82\% = \frac{0.6876}{0.83022} \times 100 \) of the variation explained by all drivers.

5.5 Drivers: purging the MDI index

When we first introduced the drivers \( D \) in section 3.2 we showed how the correlation between \( MDI \) and \( F \), 0.3187 as reported in Table 3, is the second highest. In this subsection I argue that the two variables still carry fundamentally different information. As a matter of fact, I construct a new \( MDI \) variable, \( MDI^O \), as the residual from the regression

\[
MDI_t = b_0 + b_1F_t + e_t
\]

(12)

\( MDI^O_t \) is by construction orthogonal to \( F_t \), nonetheless substituting it to the original \( MDI \) in the specification of the drivers’ matrix \( D \) I still find all the results\(^{36} \) detailed in section 4. I conclude that the difference in the \( F \) and \( MDI \) contents seems to be what is driving the results in the main specification.

6 Conclusions

To be written. Basically places the paper in a more broader context and suggest further research.

\(^{36}\) Available upon request.
7 Appendix

7.1 Proof of Proposition 1

First I show why $LB_t$ is a lower bound for the market risk premium $\mathbb{E}_t[R_{t+1}^{mkt} - R_{t,f}]$ then I derive equation (3).

Suppose markets are arbitrage free and there exist a stochastic discount factor $M$, satisfying the pricing equation (1) then by the FTAP $M > 0$ and there exist an equivalent risk-neutral measure $Q$ such that $R_f = \mathbb{E}[R_t]$ for any gross return $R^i_t$.

By definition the conditional risk neutral variance for the market return at horizon $t + 1$ can be written as

$$Var_t^Q(R_{t+1}^{mkt}) = E_t^Q[R_{t+1}^{mkt^2}] - E_t^Q[R_{t+1}^{mkt}]^2$$

where $R_{t+1}^{mkt}$ is the gross cum-dividend market return. Still from FTAP we can go back and forth from the physical probability measure and the risk-neutral one, thus $E_t^Q[R_{t+1}^{mkt^2}] = E_t[R_{t,f}M_{t+1}R_{t+1}^{mkt^2}]$ and by the definition of risk-neutral measure, $E_t^Q[R_{t+1}^{mkt}]^2 = R_{t,f}^2$, hence

$$Var_t^Q(R_{t+1}^{mkt}) = E_t[R_{t,f}M_{t+1}R_{t+1}^{mkt^2}] - R_{t,f}^2$$

dividing the above equation by the gross risk-free return $R_{t,f}$ and rearranging

$$\frac{Var_t^Q(R_{t+1}^{mkt})}{R_{t,f}} = E_t[R_{t+1}^{mkt} - R_{t,f}] + Cov_t(M_{t+1}R_{t+1}^{mkt}, R_{t+1}^{mkt})$$

if $Cov_t(M_{t+1}R_{t+1}^{mkt}, R_{t+1}^{mkt}) \leq 0$, the NCC, then $LB_t \equiv \frac{Var_t^Q(R_{t+1}^{mkt})}{R_{t,f}}$ is a lower bound for $RP_t \equiv E_t[R_{t+1}^{mkt} - R_{t,f}]$.

Next, I derive equation (3). From the definition of variance, using hats to denotes ex-dividend
quantities and letting $S$ be the cum-dividend market level

$$Var_t^Q(R_{t+1}^{mkt}) = E_t^Q\left[\left(\frac{S_{t+1}}{S_t}\right)^2\right] - E_t^Q\left[\frac{S_{t+1}}{S_t}\right]^2$$

$$= E_t^Q\left[\left(\frac{\hat{S}_{t+1}}{S_t}DY_t\right)^2\right] - R_{t,f}^2$$

$$= \frac{(DY_t)^2R_{t,f}}{(\hat{S}_t)^2}E_t^Q\left[\frac{\hat{S}_{t+1}^2}{R_{t,f}}\right] - R_{t,f}^2$$

by no arbitrage (see Martin 2016), since the options are written on $\hat{S}_t$

$$E_t^Q\left[\frac{\hat{S}_{t+1}^2}{R_{t,f}}\right] = 2 \int_0^\infty \hat{c}all_t(k) dK = 2 \left(\int_{\hat{F}_t}^{F_t} \hat{c}all_t(k) dK + \int_{F_t}^{\infty} \hat{c}all_t(k) dK\right)$$

since deep-in-the-money call options are neither liquid in practice nor intuitive to think about, it is convenient to split the range of integration for $E_t^Q\left[\frac{\hat{S}_{t+1}^2}{R_{t,f}}\right]$ into two and use the put-call parity to replace in-the-money call prices with out-of-the-money put prices. Assume that Market Dividends are paid as lump sums $D_{t+1}$ at the end of the period $[t : t + 1]$ but before $t + 1$, then the following is true

$$max(S_{t+1} - D_{t+1} - k, 0) = max(k - S_{t+1} + D_{t+1}, 0) + (S_{t+1} - D_{t+1}) - k$$

since $\hat{S}_{t+1} = S_{t+1} - D_{t+1}$

$$max(\hat{S}_{t+1} - k, 0) = max(k - \hat{S}_{t+1}, 0) + (S_{t+1} - D_{t+1}) - k$$

by linearity of the pricing equation

$$\hat{c}all_t(k) = \hat{pu}t_t(k) + \hat{S}_t - PV(D_{t+1}) - \frac{k}{R_{t,f}}$$
where \( PV(D_{t+1}) = \mathbb{E}^Q_t \left[ \frac{D_{t+1}}{R_{t,f}} \right] = (1 - DY_t) \mathbb{E}^Q_t \left[ \frac{S_{t+1}}{R_{t,f}} \right] = \frac{DY_{t+1}}{DY_t} \hat{S}_t \) and the last equality comes from \( R_{t,f} = \mathbb{E}^Q_t \left[ \frac{S_{t+1}}{S_t} \right] \). Applying the put-call parity

\[
\int_{0}^{\hat{F}_t} \text{call}_t(k) dK = \int_{0}^{\hat{F}_t} \text{put}_t(k) dK + \hat{F}_t \left( \frac{\hat{S}_t}{DY_t} - \frac{\hat{F}_t}{2R_{t,f}} \right)
\]

which implies

\[
\mathbb{E}^Q_t \left[ \frac{S_{t+1}^2}{R_{t,f}} \right] = 2 \left[ \int_{0}^{\hat{F}_t} \text{put}_t(k) dK + \hat{F}_t \left( \frac{\hat{S}_t}{DY_t} - \frac{\hat{F}_t}{2R_{t,f}} \right) + \int_{\hat{F}_t}^{\infty} \text{call}_t(k) dK \right]
\]

plugging \( \mathbb{E}^Q_t \left[ \frac{S_{t+1}^2}{R_{t,f}} \right] \) in \( Var^Q_t(R_{t+1}) = \frac{(DY_t)^2 R_{t,f}}{(S_t)^2} \mathbb{E}^Q_t \left[ \frac{S_{t+1}}{R_{t,f}} \right] - R_{t,f} \) delivers equation (3)

\[
LB_t = 2 \frac{(Q_t)^2}{(S_t)^2} \left( \int_{0}^{\hat{F}_t} \text{put}_t(k) dK + \text{call}_t(k) dK \right)
\]

### 7.2 Proof of Proposition 3

Denote homogeneous agents’ beliefs as \( \{p_t(\omega_t)\}_{\omega_t}^{T=0} \) with \( p_0(\omega_0) = p_0 = 1 \). Define a Lucas type economy where each asset pays dividends \( D_t^T = (D_0, ..., D_N) \) at \( t \). Since the space of feasible net trades is linear agent \( j \) at time \( t \) can trade (buy and sell) any asset in any (even infinitesimal) quantity \( \alpha_{j,t}^T = (\alpha_{j,t}^0, ..., \alpha_{j,t}^N) \). The problem that investor \( j \) faces is

\[
\max_{\{c_{j,t}(\omega_t),\alpha_{j,t}(\omega_t)\}_{\omega_t}^{T=0}} \sum_{t} \beta^T \sum_{\omega_t} p_t(\omega_t) u_{j,t}(c_{j,t}(\omega_t))
\]

subject to

\[
c_{j,t}(\omega_t) + \alpha_{j,t}(\omega_t)^T S_t(\omega_t) \leq \alpha_{j,t}(\omega_t)^T (S_t(\omega_t) + D_t(\omega_t)) \text{ for every } t \text{ and } \omega_t
\]
where $\beta_j^t$ is the subjective time discount factor of agent $j$ and $u_{j,t}$ is strictly incising and strictly concave. The market is required to clear in the aggregate meaning

$$C_t(\omega_t) \equiv \sum_j c_{j,t}(\omega_t) = \sum_i D_{i,t}(\omega_t) \text{ for every } t \text{ and } \omega_t$$

From the F.O.C. of agent $j$ problem with respect to $\alpha_{j,t}$

$$S_t(\omega_t) = \sum_{\omega_{t+1}} \beta_j \frac{u_{j,t+1}'(c_{j,t+1}(\omega_{t+1}))}{u_{j,t}'(c_{j,t}(\omega_t))} \frac{p_{t+1}(\omega_{t+1})}{p_t(\omega_t)} (S_{t+1}(\omega_{t+1}) + D_{t+1}(\omega_{t+1}))$$

Define for every $t$, $|\omega_t| \equiv \Omega_t$, then the market payoff matrix that can be reached from time $t$ at state $\omega_t$ is characterized by

$$Y_{t+1}(\omega_t) = \begin{bmatrix} S_{t+1}^0(1) + D_{t+1}^0(1) & \cdots & S_{t+1}^0(\Omega_{t+1}) + D_{t+1}^0(\Omega_{t+1}) \\ \vdots & \ddots & \vdots \\ S_{t+1}^N(1) + D_{t+1}^N(1) & \cdots & S_{t+1}^N(\Omega_{t+1}) + D_{t+1}^N(\Omega_{t+1}) \end{bmatrix}$$

because the market is complete $\text{rank}(Y_{t+1}(\omega_t)) = \Omega_{t+1}$ and $N + 1$ is large enough such that $N + 1 = \Omega_{t+1}$. Further define

$$z^j_{t+1}(\omega_t) = \begin{bmatrix} \beta_j \frac{u_{j,t+1}'(c_{j,t+1}(1))}{u_{j,t}'(c_{j,t}(\omega_t))} \frac{p_{t+1}(1)}{p_t(\omega_t)} \\ \vdots \\ \beta_j \frac{u_{j,t+1}'(c_{j,t+1}(\Omega_{t+1}))}{u_{j,t}'(c_{j,t}(\omega_t))} \frac{p_{t+1}(\Omega_{t+1})}{p_t(\omega_t)} \end{bmatrix}$$

thus the F.O.C. can be rewritten as

$$S_t(\omega_t) = Y_{t+1}(\omega_t)z^j_{t+1}(\omega_t)$$
and the payoff matrix $Y_{t+1}(\omega_t)$ is invertible and $z_{t+1}^i(\omega_t)$ is uniquely determined. That is for any agent $j$ and $i$

$$
\beta_j \frac{u'_{j,t+1}(c_{j,t+1}(\omega_{t+1}))}{u'_{j,t}(c_{j,t}(\omega_{t}))} p_{t+1}(\omega_{t+1}) = \beta_i \frac{u'_{i,t+1}(c_{i,t+1}(\omega_{t+1}))}{u'_{i,t}(c_{i,t}(\omega_{t}))} p_{t+1}(\omega_{t+1}) \equiv p_{t+1}(\omega_{t+1}) \frac{M_{t+1}(\omega_{t+1})}{p_t(\omega_t)} \equiv m_{t+1}(\omega_{t+1})
$$

note that the state contingent claim that pays 1 unit of consumption in state $\omega_{t+1}$ only can now be obtained through the asset allocation $\alpha_t(\omega_t)^T = (\alpha^0_t(\omega_t), ..., \alpha^N(\omega_t))$ such that

$$(\alpha^0_t(\omega_t), ..., \alpha^N_t(\omega_t)) = (1, 0, ..., 0) Y_{t+1}(\omega_{t+1})^{-1}$$

thus in a complete market any state contingent claim at any time $t$ is attainable. Define $\phi_0(\omega_{t+1})$ as the time 0 price of the contingent claim that at $t + 1$ delivers 1 unit of consumption if state $\omega_{t+1}$ realizes, then by the Law of One Price

$$
\phi_0(\omega_{t+1}) = price_0((\alpha^0_t(\omega_t), ..., \alpha^N_t(\omega_t)) = (1, 0, ..., 0) Y_{t+1}(\omega_{t+1})^{-1}
$$

the set $\{\{\phi_0(\omega_t)\}_{\omega_t}\}$ contains all the state prices of the economy, where by definition $\phi_0(\omega_0) = \phi_0 = 1$.

The fact that the market is complete enable to re-state the problem of agent $j$ as follows

$$
\max_{\{c_{j,t}(\omega_t)\}_{\omega_t}} \sum_t \beta_j \sum_{\omega_t} p_t(\omega_t) u_{j,t}(c_{j,t}(\omega_t))
$$

subject to

$$
\sum_t \sum_{\omega_t} \phi_0(\omega_t) c_{j,t}(\omega_t) \leq \sum_t \sum_{\omega_t} \phi_0(\omega_t) e_{j,t}(\omega_t)
$$

where $e_{j,t}(\omega_t)$ is the agent (exogenous) endowment at time $t$ in state $\omega_t$. From the F.O.C. of this problem

$$
\phi_0(\omega_t) = \beta_j \frac{u'_{j,t}(c_{j,t}(\omega_t))}{u'_{j,0}(c_{j,0})} p_t(\omega_t) \text{ for every } t \text{ and } \omega_t
$$
where $u_j'(c_{j,0}) = \delta_j$ and $\delta_j$ is the Lagrange multiplier, note that

$$\phi_0(\omega_t) = m_t(\omega_t) \times m_{t-1}(\omega_{t-1}) \times \ldots \times m_1(\omega_1)$$

for every $t$ and $\omega_t$

I next show that the competitive equilibrium allocations $\{\{c_{1,t}\}_t, \ldots, \{c_{J,t}\}_t\}$ are Pareto optimal. A Pareto optimal allocation is a feasible allocation, that is

$$\sum_j c_{j,0} = C_0$$

and

$$\sum_j c_{j,t}(\omega_t) = C_t(\omega_t)$$

for every $t$ and $\omega_t$

such that it does not exist any other allocation which is feasible and can strictly increase at least one individual's utility without decreasing the utilities of the others. From the classical second welfare theorem (see e.g. Varain (1978)), it is known that corresponding to every Pareto optimal allocation, there exist a set of non-negative numbers, $\{\lambda_j\}_j$, such that the same allocation can be achieved by a social planner solving the following problem

$$\max_{\{\{c_{j,t}(\omega_t)\}_t\}_j} \sum_i \lambda_j \sum_t \beta_j \sum_{\omega_t} p_t(\omega_t) u_{j,t}(c_{j,t}(\omega_t))$$

subject to

$$\sum_j c_{j,0} = C_0$$

and

$$\sum_j c_{j,t}(\omega_t) = C_t(\omega_t)$$

for every $t$ and $\omega_t$

where in order to avoid the trivial (and unrealistic) case of Pareto Optima where only some investor get something I require the Pareto weights to be strictly positive. It is then easy to show that the F.O.C of this problem are the same of these of last problem provided we set the Lagrange multipliers of this problem, $\gamma_t(\omega_t)$, equal to the state prices, i.e. $\gamma_t(\omega_t) = \phi_0(\omega_t) > 0$ and we set
the Pareto weights such that $\lambda_j = \frac{1}{\delta_j}$ where $\delta_j$ was the $j$-th Lagrange multiplier in the previous problem. Thus the competitive equilibrium allocations $\{(c_{1,t})_t, \ldots, (c_{J,t})_t\}$ are Pareto optimal.

The last step of the proof concern the construction of the single agent economy which, given the stream of endowments $\sum_t \sum_{\omega_t} e_{j,t}(\omega_t)$ for each agent $j$, is sustained by the same set $\{\phi_0(\omega_t)\}_{\omega_t}$ of state prices that sustains the competitive equilibrium in the multi-agent economies that we have defined in this proof. Define

$$\beta^t = \sum_j \frac{\lambda_j}{\sum_j \lambda_j} \beta^t_j$$

$$u_0(W_0) = \max_{\{w_{j,0}\}_j} \sum_j \lambda_j u_{j,0}(w_{j,0})$$

subject to

$$\sum_j w_{j,0} = W_0$$

$$u_t(W_t(\omega_t)) = \max_{\{w_{j,t}(\omega_t)\}_j} \frac{1}{\beta^t} \sum_j \lambda_j \beta^t_j u_{j,t}(w_{j,t}(\omega_t)) p_t(\omega_t)$$

subject to

$$\sum_j w_{j,t}(\omega_t) = W_t(\omega_t)$$

note then from the feasibility constraints it follows that

$$u'_0(C_0) = J$$

and

$$u'_t(C_t(\omega_t)) = J \frac{\phi_0(\omega_t)}{\beta^t}$$

now consider an agent whose utility function and endowments are $\sum_t \beta^t \sum_{\omega_t} p_t(\omega_t) u_t(C_t(\omega_t))$ and $\{C_t(\omega_t)\}_{\omega_t}$ respectively where $C_t(\omega_t) = \sum_j e_{j,t}(\omega_t)$ for every $t$ and $\omega_t$ so that the market clears. Then the state prices must be set so that the agent optimal consumption is to hold the aggregate endowments. Therefore, using the time 0 consumption good as the numeraire, the ratio of state prices $\frac{\phi_0(\omega_{t+1})}{\phi_0(\omega_t)}$ must be equal to the single agent’s marginal rate of substitution between time $t$ in
state \( \omega_t \) and time \( t + 1 \) in state \( \omega_{t+1} \), a necessary condition which is indeed satisfied

\[
M_{t+1}(\omega_{t+1}) \equiv \beta \frac{u'_{t+1}(C_{t+1}(\omega_{t+1})) p_{t+1}(\omega_{t+1})}{u'_t(C_t(\omega_t)) p_t(\omega_t)} = \frac{\phi_0(\omega_{t+1})}{\phi_0(\omega_t)}
\]

It is straightforward to show that the set \( \{ \phi_0(\omega_t) \}_{\omega_t} \) of state prices are indeed equilibrium prices in the economy of the single agent. As a matter of fact the agent solves

\[
\max_{\{C_t(\omega_t)\}_{\omega_t}} \sum_t \beta^t \sum_{\omega_t} p_t(\omega_t) u_t(C_t(\omega_t))
\]

subject to

\[
\sum_t \sum_{\omega_t} \phi_0(\omega_t) C_{j,t}(\omega_t) = \sum_t \sum_{\omega_t} \phi_0(\omega_t) (\sum_j e_{j,t}(\omega_t))
\]

from the F.O.C

\[
\phi_0(\omega_{t+1}) = \beta^{t+1} \frac{u'_{t+1}(C_{t+1}(\omega_{t+1}))}{u'_0(C_0)} p_{t+1}(\omega_{t+1})
\]

thus

\[
\frac{\phi_0(\omega_{t+1})}{\phi_0(\omega_t)} = \beta \frac{u'_{t+1}(C_{t+1}(\omega_{t+1}))}{u'_t(C_t(\omega_t))} \frac{p_{t+1}(\omega_{t+1})}{p_t(\omega_t)} \equiv M_{t+1}(\omega_{t+1})
\]

As a last important remark notice that the single agent utility is a function of the Pareto optimal weights \( \{ \lambda_j \}_j \) and that for each \( j \) \( \lambda_j = \frac{1}{\gamma_j} \) and \( \gamma_j \) is the Lagrange multiplier for \( (\sum_t \sum_{\omega_t} \phi_0(\omega_t) (e_{j,t}(\omega_t)) - c_{j,t}(\omega_t)) \)) so that by changing the (exogenous) endowment distribution \( \{e_{j,t}(\omega_t)\}_{\omega_t} \) or, in general, the aggregate endowment distribution \( \{\sum_j e_{j,t}(\omega_t)\}_{\omega_t} \) the equilibrium point changes and also potentially the agent that at the new equilibrium point holds the market. Because in general endowments as well as the ex-dividend asset prices \( S_t \) are functions of a set of state variables \( \{Z_{t1}, ..., Z_{ts}\} \) by changing the state variables both prices and endowments changes leading to a potential change in the single agent who holds the market.
7.3 The Ludvigson et al. 2016 financial uncertainty index \( F \) as disagreement

In this subsection I show how the financial uncertainty index \( F \), designed to capture “the conditional volatility of a disturbance that is unforeseeable from the perspective of economic agents”,\(^{37}\) can be viewed as a proxy for disagreement. Since, unlike the classical disagreement proxies available in the literature, the monthly data for \( F \) dates back to the sixties, it is particularly convenient for my study which uses an overall sample starting in February 1973.

The reason why we can think of \( F \) as a proxy for disagreement is due to the fact that its time-series can be almost replicated by a nonlinear regression which is only a function of the classical disagreement proxies available in the literature and the Rapach et al. (2016) short interest index \( SII \) (also being a proxy for disagreement). In particular, on top of \( SII \) I use the standard deviation of the \( I/B/E/S \) time-series of 1-year \( SP500 \) top.down earning-per-share analysts’ forecasts (available from January 1992), \( EPS^{TD} \), the Yu (2011) bottom-up disagreement measure computed by aggregating disagreements regarding the individual assets in the \( SP500 \) portfolio (available from January 1982 to December 2011), \( EPS^{BU} \), and the Carlin et al. (2014) disagreement measure calculated as the level of disagreement among Wall Street mortgage dealers about prepayment speeds (available from January 1993 to December 2012), \( CLM \).

The following graph shows the time-series of \( F \) and \( \hat{F}_t \), the estimate of \( F \) from the model

\[
F_t = \beta_0 + f(EPS^{TD}, EPS^{BU}, CLM, SII) + u_t
\]

where \( f(\cdot) \) is a full second order polynomial in its arguments.

\(^{37}\)See Ludvigson et al. 2016
The adjusted $R^2$ of the regression is 0.8028 while the correlation between the two time-series is 0.9038.

### 7.4 The fundamental difference between $F$ and $ILLIQ$

This subsection is basically an extension of the previous one: in order to show the difference in nature of the two indexes despite a correlation of 0.3743, I repeat the analysis conducted on $F$ to $ILLIQ$. The model is

$$ILLIQ_t = \beta_0 + f(EPS^{TD}, EPS^{BU}, CLM, SII) + u_t$$

where $f(\cdot)$ is a full second order polynomial in its arguments. This time, very differently from the case of $F$ I find a regression adjusted $R^2$ of approximately 2%. I conclude that $ILLIQ$, unlike $F$, cannot be replicated by disagreement proxies, thus containing fundamentally different information.

### 7.5 The tight link between $ILLIQ$ and the bid-ask spread on the market

Yet to be written. Basically we document the positive correlation between the mid-ask spread on the market and the illiquidity index and that the market bid-ask spread Granger causes illiquity.
7.6 Low Demand for the Market Portfolio

The last piece of evidence I gather in the static analysis of the RAEMs failures concerns the investors’ aggregate reaction: we already documented that the RAEMs rejections periods are characterized by times of high market illiquidity, disagreement and irrationally downward biased expectations. This section investigate how the market demand in these periods look like which is ultimatly an empirical question: as a matter of fact we gathered confounding evidence with this respect. On the one hand investors’ optimism should trigger demand while on the other hand uncertainty and illiquidity should depress it. In order to let the data speak we implement a model specification very similar to (9) and (10)

\[ q_t = \delta_1 I^v_t + \delta_2 (1 - I^v_t) + \psi_t \quad (13) \]

where \( q_t \) is a proxy for the demand of the market portfolio. The next table illustrates the results for this subsection

<table>
<thead>
<tr>
<th>Coeff.</th>
<th>( Vol_{t+1} )</th>
<th>( SII_{t+1} )</th>
<th>( NetEquityPurch_{t+1} )</th>
</tr>
</thead>
<tbody>
<tr>
<td>( \delta_1 )</td>
<td>0.2944***</td>
<td>0.7927***</td>
<td>2977***</td>
</tr>
<tr>
<td>( \delta_2 )</td>
<td>-0.0869</td>
<td>-0.1419</td>
<td>5569</td>
</tr>
<tr>
<td>( \delta_1 - \delta_2 )</td>
<td>0.3813***</td>
<td>0.9346***</td>
<td>-2592**</td>
</tr>
</tbody>
</table>

The table shows the result from the regression \( q_{t+1} = \delta_1 I^v_t + \delta_2 (1 - I^v_t) + \psi_{t+1} \) over the main sample Jan : 1990 - Dec : 2014. \( q_{t+1} \) is a proxy for the demand for the market portfolio in \( t + 1 \) and \( I^v_t \) is a non-negative step function \( I^v \equiv 1_{[\hat{\pi}_{t+1} < LB_t]} \) isolating the periods in which the RAEMs are rejected at the 5% level. Three proxies for \( q_{t+1} \), corresponding to the different columns, are used: the de-trended log volume of SPDR SP500 ETF (measured as the log of the number of shares sold), \( Vol \), the Rapach et al. (2016) short interest index \( SII \) and the the net purchase position (purchases-sales) in U.S. equity from foreign investors, \( NetEquityPurch \). One star symbols the statistic is significantly different from zero at the 10% level, two stars at the 5% and three stars at the 1%.

Three proxies for the market portfolio demand are used: the de-trended log volume of SPDR SP500 ETF (measured as the log of the number of shares sold), Vol, the Rapach et al. (2016) short interest index SII and the the net purchase position (purchases-sales) in U.S. equity from foreign investors, NetEquityPurch. $\delta_1$ is statistically different from zero (positive) at the 1% level in all the specifications. Furthermore, $\delta_1$ is statistically different (greater) than $\delta_2$ when the demand proxies are the (log) number of SP500 ETFs sold, Vol, and the aggregate equity volume shorted SII while the opposite occur for the case in which the demand proxy is the net purchase of U.S. equities from foreign investors. Overall these evidence document how investors’ demand for the market portfolio is lower during RAEMs rejections periods.

### 7.7 Forecasting the Unemployment and the Spread between BAA corporate yields and the federal funds rate

In this subsection I show how I specified, following the Box-Jenkins (1970) procedure, the forecasting models for the Unemployment rate, $UR$, and the spread between the BAA rated corporate bonds and the federal funds rate, $SP$, yielding the time-series for the conditional expectations $E_t[UR_{t+1}]$ and $E_t[SP_{t+1}]$ respectively.

For both time-series I used the autocorrelation and partial autocorrelation functions and plotted the first differences in order to generate a set of candidate parameters for the ARIMA class of time-series model to be used, then I exploited the AIC and BIC criteria to select the optimal set of parameters and finally performed an Augmented Dickey-Fuller test to check for stationarity. The time-series of conditional expectations, $E_t[y_{t+1}]$ with $y \in \{UR, SP\}$, are computed as iterative out-of-sample one-step ahead forecasts using the best specified stationary ARMIA model. If the model is correctly specified, the innovations $\varepsilon_{t+1} = y_{t+1} - E_t[y_{t+1}]$ should be independent over time and have zero mean.\(^{39}\)

The results are displayed in the graphs below.

\(^{38}\)The result still hold without the de-trending but time-series graphs (available upon request) show it might wrongly pick up some time effects.

\(^{39}\)Which is not guaranteed by construction since the forecast are out of sample.
as shown in the upper autocorrelation plot for $\varepsilon_{UR}$, the best selected ARIMA model, calibrated in the sample Jan : 1948 – Dec : 1989, features a first difference in $UR$ to which an AR process of order 3 has been applied and generates out-of-sample innovations with no systematic (linear) dependence and a mean not statistically significant from zero. The bottom graph reports the analogous analysis for the case of $SP$; results are similar to those of $UR$ except that the best selected model, calibrated in the sample July : 1954 – Dec : 1989, is an ARIMA(4,1,0), i.e. the first difference of $SP$ is modeled through an AR process of order 4.

The table summarizes the selected drivers $D$ over the entire sample $Feb : 1973 – Dec : 2014$. $F$ is the Ludvigson et al. (2016) financial uncertainty measure: computed as the cross-sectional average conditional volatility of the 1-month Root Mean Squared Error in predictive regressions over approximately 150 monthly financial time series. $SII$ is the Rapach et al. (2016) short interest index: computed as the log of the equal-weighted mean of short interest (as a percentage of share outstanding) across all publicly listed stocks on U.S. exchanges. $TAXchg$ is the annual time series of the rate of change on total taxes paid on capital gains as reported by the U.S. Department of Treasury. $ILLIQ$ is the negative of the Pastor-Stambaugh (2003) liquidity index: computed as the (negative of the) aggregate daily response (average over a month) of signed volume to next day return for all individual stocks on the New York Stock Exchange and the American Stock Exchange. $MDI$ is the Pasquariello (2014) Market Dislocation Index: computed as a monthly average of hundreds of individual abnormal absolute violations of three textbook arbitrage parities in stocks, foreign exchange and money markets. $BM$ is the book-to-market value ratio for the Dow Jones Industrial Average. $USDg$ is the U.S. Dollar appreciation index: computed as the linear return on the Trade Weighted U.S. Dollar Index available from the Saint Louis Federal Reserve; the index is a weighted (over the volume of bilateral transactions) average of the foreign exchange value of the U.S. dollar against the currencies of a broad group of major U.S. trading partners.

The table reports the result (omitting the constant term) from the regression $I_t^v = \beta_0 + D_t\beta + u_t$ ranked by partial $R^2$ on the $\beta$ coefficients over the main sample Jan : 1990 – Dec : 2014. $I_t^v$ is a non-negative step function $I_t^v \equiv 1_{[\hat{\pi}_{t+1} < LB_t]}$ isolating the periods in which the RAEMs are rejected at the 5% level, while $D_t$ is the matrix of selected drivers (For a description of the drivers see notes to Table 2). The last column shows the adjusted $R^2$ of the regression when $D_t$ only includes the first three most important drivers (i.e. $F$, $SII$ and $ILLIQ$). One star symbols the statistic is significantly different from zero at the 10% level, two stars at the 5% and three stars at the 1%.

The table shows the result from the regression $d_t = \alpha_1 I_t^v + \alpha_2 (1 - I_t^v) + w_t$ over the main sample Jan : 1990 – Dec : 2014. $d_t \in \{F_t, SII_t, ILLIQ_t\}$ is one among the main drivers while $I_t^v$ is a non-negative step function $I_t^v \equiv 1[\hat{\pi}_{t+1} < LB_t]$ isolating the periods in which the RAEMs are rejected at the 5% level. Rows three and four report whether or not the estimate for $\alpha_1$ is statistically greater than the unconditional median and 75-th percentile. One star symbolizes the statistic is significantly different from zero at the 10% level, two stars at the 5% and three stars at the 1%.

</tbody>
</table>

The table shows the result from the regression $z_{t+1} - E_t[z_{t+1}] = \gamma_1 I^e_t + \gamma_2 (1 - I^e_t) + \eta_{t+1}$ over the main sample Jan : 1990 – Dec : 2014. $z_{t+1}$ is the random variable according to which investors form expectations $E_t[z_{t+1}]$, while $I^e_t$ is a non-negative step function $I^e_t = 1[\pi_{t+1} \leq LB_t]$ isolating the periods in which the RAEMs are rejected at the 5% level. In the first five columns $z_{t+1}$ represents the return of the market in excess of the risk-free rate and expectations are collected from survey data (Gallup, American Association of Individual Investors, Shiller, Graham and Harley, and Michigan) validated in Greenwood-Shleifer (2014). $z_{t+1}$ in the sixth column represent inflation, Infl and the expectations are the market implied (and priced) ones from the difference in the yield of 5-year inflation indexed treasury bonds and the yield of 5-year nominal treasury bonds. In the last two columns $z_{t+1}$ captures a key economic indicator, the U.S unemployment rate, $UR$, and a core financial indicator, the spread between the BAA rated corporate bonds and the federal funds rate, $SP$; expectations in this case are computed as forecasts through the specification of an econometric model following the Box-Jenkins (1970) procedure (See Appendix for the details on the specification procedure). One star symbol the statistic is significantly different from zero at the 10% level, two stars at the 5% and three stars at the 1%, $X_t$ indicates the statistic $X$ has a p-value greater than 0.3.

</table>

The table shows the summary statistic of the empirical distribution in the main sample Jan : 1990 − Dec : 2014 of the lower bound measures computed through (3). \(LB^m_M\), with \(m \in \{l, cs\}\), corresponds to the case the dividend yield \(DY\) is set to 1, which is the Martin (2016) formulation, \(m \in \{l, cs\}\) being the measure calculated via the linear and the cubic-spline approximation. \(LB^m\), represents the measure which uses the SP500 dividends from Shiller.

Table 11: RAEMs’ rejections driven by negative market returns

| Statistic | \(y|I^v\) | \(\pi|I^v\) | \(R^{mkt}|I^v\) | \(\bar{R}_f\) | \(\bar{LB}\) |
|-----------|-----------|-----------|----------------|-------------|-------------|
| Cond.Mean | -0.0133** |           |                |             |             |
| Cond.Mean | -0.010    |           |                | 0.003       |             |
| Cond.Mean | -0.004    |           |                | 0.003       |             |

The table summarizes the statistics in the main sample Jan : 1990 − Dec : 2014 concerning the joint model free test for the RAEMs detailed in Definition 2 and Table 5. Differently from the main test reported in Table 5, this one fixes the risk-free rate and the lower bound measure to their unconditional mean, \(\bar{R}_f\), and \(\bar{LB}\) respectively. One star symbols the statistic is significantly different from zero at the 10% level, two stars at the 5% and three stars at the 1%.

The table reports the result (omitting the constant term) from the regression $P_t(\pi_{t+1} < LB_t) = \beta_0 + D_t \beta + u_t$ ranked by partial $R^2$ on the $\beta$ coefficients over the main sample Jan : 1990 – Dec : 2014. $P_t(\pi_{t+1} < LB_t)$ is the conditional probability to reject the RAEMs at time $t$ introduced in section 2.2.2, while $D_t$ is the matrix of selected drivers (For a description of the drivers see notes to Table 2). The last column shows the adjusted $R^2$ of the regression when $D_t$ only includes the first three most important drivers (i.e. $F$, $SII$ and $ILLIQ$). One star symbols the statistic is significantly different from zero at the 10% level, two stars at the 5% and three stars at the 1%.
10 Figures

Figure 1: Bid-ask spread surface with information ambiguity

The figure plots the bid-ask spread surface from Aliyev and He (2016a) as a function of the aversion to ambiguity/pessimism, \( \alpha \) (with \( \alpha = 0 \) representing a fully ambiguous-averse/pessimistic attitude) and the level of ambiguity/uncertainty, \( \delta \). (with \( \delta = 1 \) corresponding to fully ambiguous information) The horizontal plane is the bid-ask spread in the classical rational benchmark of Glosten and Milgrom (1985).
Figure 2: Horse-race for the best model for predicting $\pi_{t+1}$

The blue solid line plots the actual excess return, $\pi_{t+1}$, the $OLS$ forecasts, $\pi_{t+1}^{OLS}$, are displayed by a red dashed line while the dot-dash green line shows the $IMC$ forecasts, $\pi_{t+1}^{IMC}$: the top panel illustrates the in-sample forecasts against the actual data in the training sample $TS$, while the bottom one the one-step ahead out-of sample estimates in the main sample $MS$. The models are compared, both in and out of sample, in terms of their coefficients and $R^2$ in the following regression

$$\pi_{t+1} = \alpha + \beta \pi_{t+1}^{Mod} + u_{t+1} \text{ with } Mod \in \{OLS, IMC\}$$

a good model should have $\alpha = 0$, $\beta = 1$ and an high $R^2$. The estimates of these parameters are reported in the legends.
The autocorrelation function of $y_{t+1} \equiv \pi_{t+1} - LB_t$ ($\pi_{t+1} \equiv R_{t+1}^{mkt} - R_{t,f}$ being the excess market return and $LB_t$ the lower bound measure for the risk premium $E_t[\pi_{t+1}]$ computed through (3)) together with the 95% confidence bands.
Figure 4: joint RAEMs rejection periods

The figure displays in solid blue the time series of $y_{t+1} \equiv \pi_{t+1} - LB_t$ ($\pi_{t+1} \equiv R^{mt}_{t+1} - R_{t,f}$ being the excess market return and $LB_t$ the lower bound measure for the risk premium $E_t[\pi_{t+1}]$ computed through (3)) while in dashed red the time series highlighting the sub-sample in which the RAEMs are jointly rejected at the 5% level. The pink shaded areas emphasize the NBER recessions.
Figure 5: conditional probability to reject the RAEMs

The figure displays the conditional probability to reject the RAEMs: the upper graph plots the time-series, solid blue line, against the negative of the U.S. GDP growth, dashed line, and the pink areas represents the NBER recession over the main sample Jan : 1990 – Dec : 2014. The lower graph illustrates the empirical distribution against the lognormal benchmark and reports the minimum the 25-th, the 50-th, the 75-th quantiles and the maximum.
Figure 6: different motivations behind RAEMs’ failures over time

The figure displays the contribution to the conditional probability to reject the RAEMs of the main drivers: in the upper graph the joint contribution of the disagreement proxies $F,SII$ is plotted in the form of a dashed red line, the contribution of the illiquidity index $ILLIQ$, is represented by a dotted green line, while the overall conditional probability of rejecting the RAEMs is still a solid blue line as in Figure 3. In the bottom graph the solid light blue line tracks the difference between the disagreement and the illiquidity series; positive values indicate an higher contribution of disagreement (asymmetric information) while negative values a predominant contribution of illiquidity (market frictions).
Figure 7: The lower bound measure: linear versus cubic-spline interpolation

The figure displays the two different interpolation scheme adopted in the study to compute the lower bound measure according to equation (3). The upper graph plots the two time-series of lower bounds under the different interpolations, while the bottom one shows, in percentage, the absolute difference in terms of the cubic-spline approximation.
